Various clostridial species, particularly *Clostridium perfringens*, *Clostridium chauvoei*, *Clostridium septicum*, and *Clostridium novyi*, can elaborate toxins (Table 15-4) that damage myofibers and intramuscular vasculature, resulting in hemorrhagic myonecrosis (Figs. 15-36 and 15-42). Toxemia is typical and is often lethal. Clostridial myositis is most common in cattle and horses. Clostridial myositis has also been called gas gangrene and malignant edema in horses and blackleg in cattle.

Pyogenic bacteria introduced into a muscle usually cause localized suppuration and myofiber necrosis. This may resolve completely or become localized to form an abscess. In some cases, the infection can spread down the fascial planes (Fig. 15-15). For example, a nonsterile intramuscular injection into the

## Pathologic Basis of Veterinary Disease, 4th Edition

gluteal muscles of cattle can cause an infection that extends down the fascial planes of the muscles of the femur and tibia and erupts to the surface through a sinus proximal to the tarsus. Although the majority of inflammation involves fascial planes, some bacteria extend into and cause necrosis of adjacent muscle fasciculi. *Streptococcus zooepidemicus* (horses), *Arcanobacterium pyogenes* (cattle and sheep), and *Corynebacterium pseudotuberculosis* (horses, sheep, and goats) are common causes of muscle abscesses. After bite wounds, cats can develop cellulitis caused by *Pasteurella multocida* that extends into the adjacent muscle.

Bacteria causing single or multiple granulomas (focal or multifocal granulomatous myositis) are relatively uncommon. Most such lesions are caused by *Mycobacterium bovis* (tuberculosis), usually in cattle and pigs, but this is rare in North America.

Chronic fibrosing nodular myositis of the tongue musculature in cattle is the result of infection with *Actinobacillus lignieresii* (wooden tongue) or *Actinomyces bovis* (the agent causing lumpy jaw). A similar lesion caused by *Staphylococcus aureus* and known as botryomycosis is most commonly seen in horses and pigs. It is most often wound related and can occur at a variety of sites. Histologically, actinobacillosis, actinomycosis, and botryomycosis are similar in that the lesions are encapsulated inflammatory lesions containing a central focus of “radiating clubs” of amorphous eosinophilic material associated with bacteria and neutrophils (Splendore-Hoeppli reaction). Neutrophils admixed with macrophages (pyogranulomatous inflammation) can also be seen. Gram stained tissue can differentiate the clusters of gram-positive cocci in *Staphylococcus* infection, the gram-positive bacilli causing actinomycosis (*Actinomyces bovis*), and the gram-negative bacilli causing actinobacillosis (*Actinobacillus lignieresii*).

Table 15-7 Viral Myopathies

RNA VIRUSES		
Disease	Family	Causal Agent
Porcine encephalomyelitis	Picornaviridae	Enterovirus
Foot-and-mouth disease	Picornaviridae	Aphthovirus
Bluetongue	Reoviridae	Orbivirus
Akabane disease	Bunyaviridae	Akabane virus

### 15.2.1.2.2 Viral

Relatively few of these are recognized in veterinary medicine. Spontaneous ones are listed in [Table 15-7](#). Gross lesions may or may not be visible and, if present, are small, poorly defined foci or streaks. Muscle lesions induced by viruses are either infarcts secondary to a vasculitis, as seen in bluetongue in sheep, or multifocal necrosis, presumably because of a direct effect of the virus on the myofibers.

### 15.2.1.2.3 Parasitic

Parasitic infections of the skeletal muscles of domestic animals are not uncommon and include protozoal organisms and nematodes. The most important ones are listed in [Table 15-8](#) and are discussed under the appropriate species heading. Most parasitic diseases are of little pathologic or economic importance, with the exception of *Neospora caninum*, *Hepatozoon americanus*, and *Trypanosoma cruzi* in dogs, and *Trichinella spiralis* in pigs.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 15-8 Parasitic Myopathies

Infectious Agent	Species Affected
<i>Sarcocystis</i> spp.	Horses, cattle, sheep, goats, camelids, pigs
<i>Trichinella spiralis</i>	Pigs
<i>Neospora caninum</i>	Dogs, fetal cattle
<i>Trypanosoma cruzi</i>	Dogs
<i>Cysticercus</i> spp.	Cattle, sheep, goats, pigs
Nematode larval migrans	Dogs
<i>Hepatozoon americanum</i>	Dogs

1000

As the name *Sarcocystis* suggests, intramyofiber protozoal cysts caused by *Sarcocystis* spp. are a common finding. This protozoal organism is a stage of an intestinal coccidium of carnivores that uses birds, reptiles, rodents, pigs, and herbivores as an intermediate host. Ingestion of oocysts by an intermediate host releases sporozoites that invade tissue, including muscle. This parasite rarely causes clinical disease and is therefore most often considered an incidental finding. *Sarcocystis* infection of muscle is seen most often in horses, cattle, and small ruminants and occasionally in cats. Because they are intracellular, cysts are protected from the host's defense mechanisms; thus there is no inflammatory response (Fig. 15-31).

1001

### 15.2.1.2.4

#### Immune-Mediated

Immunologically induced myositis, not associated with vascular injury, has to-date been recognized primarily in the dog. Rarely, immune-mediated myositis occurs in cats and horses. Infiltrating lymphocytes, most often cytotoxic T lymphocytes, are the cause of myofiber injury. Although cytotoxic T lymphocytes are the effector cells causing myofiber damage, the inflammatory infiltrate will be a mixture of lymphocyte types. The characteristic histologic pattern of immune-mediated myositis is an interstitial and perivascular lymphocytic infiltration (Fig. 15-32, A; Fig. 15-52), often with invasion of intact myofibers by lymphocytes (Fig. 15-32, B). A variety of forms of immune-mediated myositis occur in the dog and can be localized to specific muscles because of proven or suspected unique myosin isoforms within those muscles. These are listed in Table 15-9. Acquired myasthenia gravis is also an immune-mediated disease included in this table for completeness, but this is a disorder causing damage to the neuromuscular junction rather than to myofibers. In cats, feline immunodeficiency virus infection is a cause of immune-mediated myositis. In horses, lesions consistent with immune-mediated myositis are occasionally found following exposure to *Streptococcus equi* ssp. *equior* infection with equine influenza virus. It should be pointed out that small perivascular and interstitial infiltrates of lymphocytes, with no apparent myofiber damage, are a frequent incidental finding in equine muscle.

1001

1002

**Fig. 15-31 Sarcocystosis, skeletal muscle, longitudinal section, cow.**

The elongate encysted intramyofiber protozoan is characteristic of *Sarcocystis* spp. There is no associated inflammation. These parasites are common in the muscles of many species of domestic animals and are usually an incidental finding. Formalin fixation, H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 15-32 **Immune-mediated myositis, canine polymyositis, skeletal muscle, transverse sections, dog.** **A**, There is a dense interstitial infiltrate of primarily mononuclear inflammatory cells. Formalin fixation, H&E stain. **B**, Note the interstitial infiltrate of mononuclear inflammatory cells and mononuclear cells that have invaded an intact myofibers causing myofiber necrosis. Cooper, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Table 15-9 Immune-Mediated Muscle Disorders

Disorder	Species Affected
Purpura hemorrhagica	Horses
Viral-associated	Horses, cats
Polymyositis	Dogs
Masticatory myositis	Dogs
Extraocular muscle myositis	Dogs
Acquired myasthenia gravis	Dogs, cats

Immune-mediated vasculitis resulting in muscle injury occurs in horses and is known as purpura hemorrhagica. Purpura hemorrhagica has been classically associated with *Streptococcus equi* ssp. *equi*, but other bacteria such as *Corynebacterium pseudotuberculosis* can also cause purpura hemorrhagica.

### 15.2.1.3 CONGENITAL AND INHERITED DISORDERS

Muscle is subject to numerous hereditary, congenital, and neonatal defects ([Table 15-10](#)). Muscular disorders that are apparent at birth are congenital, but they may or may not be inherited. Inherited disorders can manifest at birth or soon thereafter, or they may not be apparent for many years. Molecular biologic studies and development of molecular genetic tests have greatly enhanced our understanding of several muscular disorders of animals and the ability to detect affected and carrier animals.

#### 15.2.1.3.1 Anatomic Defects

Anatomic defects in skeletal muscle are apparent at birth or soon thereafter. These defects can be either genetic or acquired and result from either abnormal muscle development or abnormal innervation.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 15-10 Confirmed or Suspected Inherited Myopathies in Animals

Disorder	Species Affected	Inheritance
Muscular hyperplasia	Cattle	Autosomal recessive
Myotonia	Horses	Unknown
	Goats	Autosomal dominant
	Dogs	Autosomal recessive
	Cats	Unknown
HYPP	Horses	Autosomal dominant?
Glycogenoses	Horses	Autosomal recessive (glycogen brancher enzyme defect)
		Autosomal dominant (polysaccharide storage myopathy)
	Cattle	Autosomal recessive
	Sheep	Autosomal recessive
	Dogs	Autosomal recessive
	Cats	Autosomal recessive
Mitochondrial myopathy	Horses, dogs	Unknown
Duchenne's type muscular dystrophy	Dogs, cats	X-linked
Inherited myopathy ("muscular dystrophy")	Cattle, sheep	Autosomal recessive
Sarcoglycans deficient muscular dystrophy	Dogs	Autosomal recessive?
Malignant hyperthermia	Horses	Unknown
	Pigs	Autosomal recessive
	Dogs	Autosomal dominant
Labrador myopathy	Dogs	Autosomal recessive
Congenital myasthenia gravis	Dogs	Autosomal recessive
	Cats	Autosomal recessive?
HYPP, Hyperkalemic periodic paralysis.		
Question marks denote that inheritance pattern is suspected but not proven.		

### 15.2.1.3.1.1

#### Innervation defects

Congenital defects in the lower motor neuron system, involving motor neurons or peripheral nerves, will result in severe alteration of myofiber development. Denervation occurring in fetal and neonatal animals can result in very complex muscle lesions because of the importance of innervation in myofiber development and maturation. Depending on the nature of the nervous system defect, muscular lesions can reflect failure of innervation, denervation of previously innervated fibers, or a combination of both. The most common example of this is arthrogryposis in cattle and sheep in which in utero infection or toxin ingestion causes central and/or peripheral nervous system lesions leading to failure of innervation or to denervation of skeletal muscle. Failure of innervation or severe denervation injury in utero most often result in failure of the myofibers to develop and their subsequent replacement by adipose tissue (fatty infiltration). This outcome can be severe in affected muscle and may be the basis for some cases of congenital muscular steatosis in livestock (Figs. 15-11, D and 15-29).

1002

15.2.1.3.1.2

### Genetic defects

The only genetic defect recognized as causing congenital anatomic defects in animals is congenital muscular hyperplasia (double muscling) in cattle. It is possible that with continued selective breeding and advancement in molecular biologic techniques, other defects may occur or be recognized.

15.2.1.3.1.3

### Failure of normal development

In addition to failure of myofiber maturation due to innervation defects, inherent myofibrillar developmental defects can occur. This is exemplified by myofibrillar hypoplasia causing splayleg in neonatal pigs. A similar condition has been reported in a calf.

Congenital defects in the diaphragmatic muscle (diaphragmatic hernia) can occur in all species but are most well documented in dogs and rabbits. A genetic basis with a multifactor inheritance is suspected. Clinical signs of respiratory distress due to herniation of abdominal viscera into the thoracic cavity generally occur at or shortly after birth. Defects in the left dorsolateral and central portions of the diaphragm because of failure of closure of the left pleuroperitoneal canal are most common.

15.2.1.3.2

### Muscular Dystrophy

The term “muscular dystrophy” has been grossly misused in the veterinary literature. In the 1930s, the term “nutritional muscular dystrophy” was applied to a disease more appropriately classified as nutritional myopathy, and the misuse of this term has been a source of confusion for years as to exactly what is meant by muscular dystrophy. Following the definition applied to human beings, muscular dystrophy is an inherited, progressive, degenerative primary disease of the myofiber characterized histologically by ongoing myofiber necrosis and regeneration (polyphasic necrosis). Several types of muscular dystrophy occur in human beings and animals. The enormous recent advances in genetic and molecular characterization of muscle diseases have resulted in defining their exact genetic defects, such as those in the dystrophin gene responsible for Duchenne's muscular dystrophy and trinucleotide repeat sequences in myotonic dystrophy, and in the reclassification of others. Similarly, reevaluation of some inherited disorders previously classified as muscular dystrophy, such as muscular dystrophy in sheep and cattle, suggests that they would be better classified as progressive congenital myopathies.

15.2.1.3.3

### Congenital Myopathies

Those inherited disorders of muscle that do not qualify as anatomic defects, muscular dystrophy, myotonia, or metabolic myopathy (see later discussion) are classified as congenital myopathies. These include structural defects leading to abnormal myofiber cytoarchitecture. In some cases, a specific gene defect is known, whereas the cause of others remains undetermined.

15.2.1.3.4

### Myotonia (Channelopathies)

Myotonia is defined as the inability of skeletal muscle fibers to relax, resulting in spasmodic contraction. Various inherited myotonic conditions have been recognized in human beings and animals for many years. Only recently has the basis for many of these myopathies been determined. Most have been found to relate to inherited defects resulting in abnormal ion channel function. Maintenance of ionic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

equilibrium and control of the ionic fluxes associated with excitable tissue such as muscle are critical to normal muscle functioning. A variety of sarcolemmal ion channels exist that control fluxes of ions such as sodium, potassium, chloride, and calcium. Defective sodium or chloride channels most often result in myotonia.

15.2.1.3.5

### Metabolic Myopathies

Inherited disorders of muscle metabolism ([Table 15-10](#)) are characterized by reduced muscle cell energy production. Clinical signs include exercise intolerance, exercise-induced muscle cramps, and rhabdomyolysis. Metabolic defects can involve glycogen metabolism, fatty acid metabolism, or mitochondrial function. Metabolic disorders often cause increased blood lactate after exercise. Inheritance patterns vary. Glycolytic, glycogenolytic, and nonmitochondrial DNA–encoded enzyme defects are generally inherited in an autosomal recessive manner. Defects involving mitochondrial DNA–encoded enzymes are inherited through maternal inheritance, because all mitochondria are contributed from the oocyte.

The pathways of glycolysis and glycogenolysis are complex, involving a cascade of enzymatic reactions. Deficiency of a glycolytic or glycogenolytic enzyme leads to accumulation of glycogen and in some cases glycogen-related proteoglycans. There are several different types of glycogen storage diseases depending on which enzyme is deficient. Several types of glycogenoses are recognized in human beings, and five (types II, III, IV, V and VII) cause glycogen accumulation in muscle. Of the glycogenoses affecting muscle, only types II (acid maltase deficiency), IV (glycogen branching enzyme deficiency), V (myophosphorylase deficiency), and VII (phosphofructokinase deficiency) have so far been recognized in animals. Storage diseases in which glycogen accumulates in muscle have been described in horses, cattle, sheep, dogs, and cats.

Inherited lipid storage myopathies have not yet been described in animals, although dogs appear to have a predilection for development of neuromuscular weakness because of acquired lipid storage myopathy with concurrent reduction in skeletal muscle carnitine activity. Mitochondrial myopathies are rarely recognized in animals, perhaps because of the difficulty in documentation of mitochondrial defects. A few such disorders have been described in dogs, and a mitochondrial myopathy has been reported in one Arabian horse. Mitochondrial disorders may affect only muscle, or muscle involvement may be part of an encephalomyopathic condition.

1003

1004

15.2.1.3.6

### Malignant Hyperthermia

Malignant hyperthermia is a condition characterized by unregulated release of calcium from the sarcoplasmic reticulum, leading to excessive myofiber contraction that causes a severe increase in body temperature. Malignant hyperthermia is often fatal. In human beings, pigs, horses, and dogs a congenital defect in the sarcoplasmic reticulum calcium-release channel, the ryanodine receptor, causes dysregulation of excitation-contraction coupling leading to malignant hyperthermia. Episodes in affected individuals can be triggered by general anesthetic agents, especially halothane, or by stress—hence the name *porcine stress syndrome* for the disorder in pigs ([Fig. 15-47](#)).

A malignant hyperthermia-like condition can also occur because of other myopathic conditions, especially those that result in uncoupling of mitochondrial oxidative phosphorylation from the electron transport chain. Inherently uncoupled mitochondria within brown fat are the physiologic basis for

## Pathologic Basis of Veterinary Disease, 4th Edition

production of heat during breakdown of this fat in neonates, and pathologically uncoupled or loosely coupled mitochondria in muscle as a result of an underlying myopathy will also release energy as heat.

Gross and microscopic lesions are described in the section covering the disorder in pigs.

### 15.2.1.4 ENDOCRINE AND ELECTROLYTE ABNORMALITIES

Various endocrinologic abnormalities can result in myopathic conditions ([Table 15-11](#)). The most common are hypercortisolism and hypothyroidism in dogs. In horses, pituitary hyperfunction resulting in Cushing's disease is also associated with muscle disease. In most cases of endocrine myopathy, the end result is myofiber atrophy, particularly of type 2 fibers. A unique syndrome of muscle hypertrophy and pseudomyotonia occurs in dogs associated with hypercortisolism. Endocrine myopathies can also be complicated by pathologic changes in peripheral nerves, leading to a mixture of myopathic (type 2 fiber atrophy) and neuropathic changes (denervation atrophy and alteration in fiber-type pattern) within muscle. Denervation followed by reinnervation leading to fiber-type grouping can be seen in dogs with chronic hypercortisolism ([Fig. 15-24, B](#)) and hypothyroidism.

**Table 15-11 Myopathies Due to Endocrine and Electrolyte Abnormalities**

Disorder	Species Affected
Hypothyroidism	Dogs
Hypercortisolism	Dogs
Hypokalemia	Cattle, cats
Hypophosphatemia	Cattle
Hypernatremia	Cats
Hypocalcemia	Cattle
Hypothalamic/pituitary dysfunction	Horses

Normal electrolyte status is vital to normal skeletal muscle function. Hypocalcemia, hypokalemia, hypernatremia, and hypophosphatemia can cause profound skeletal muscle weakness, sometimes associated with myofiber necrosis, in various species.

### 15.2.1.5 NEUROPATHIC AND NEUROMUSCULAR JUNCTION DISORDERS

Dysfunction of the lower motor neurons, peripheral nerves, or neuromuscular junction can have profound effects on muscle function.

#### 15.2.1.5.1 Neuropathic Disorders

There are many peripheral nerve disorders, and fewer motor neuron disorders, that can lead to denervation atrophy of muscle in animals. These can be inherited or acquired. Long nerves such as the sciatic and left recurrent laryngeal nerves appear to be particularly sensitive to development of acquired neuropathy. Many of the peripheral nerve disorders of animals are discussed in [Chapter 14](#). Characteristic features of denervation atrophy are described in this chapter under Response of Muscle to Injury.

### 15.2.1.5.2

#### Neuromuscular Junction Disorders

The neuromuscular junction is a modification of the postsynaptic myofiber membrane. At the neuromuscular junction, the membrane is folded to increase surface area and is studded with specialized ion channels known as acetylcholine receptors. Following arrival of an action potential at the distal end of a motor nerve, the terminal axons release acetylcholine, which diffuses across the synaptic space to bind to the acetylcholine receptors. Binding opens these channels, leading to sodium influx, which initiates the skeletal muscle action potential that culminates in muscle contraction. Acetylcholine is rapidly degraded by acetylcholinesterase released from the postsynaptic membrane, which prevents continued stimulation of the muscle fiber.

Disorders that impair the ability of nerve impulses to travel across the neuromuscular junction have profound effects on skeletal muscle function. Technically, however, the myofibers are still innervated, so denervation atrophy does not occur, and no light microscopic abnormalities in the muscle or nerve are present. Various neurotoxins (i.e., in snake and spider venom) and drugs can affect the neuromuscular junction, but the most common neuromuscular junction disorders affecting animals are myasthenia gravis, botulism, and tick paralysis.

1004

1005

### 15.2.1.5.2.1

#### Myasthenia gravis

Myasthenia gravis can be either acquired or congenital. Acquired myasthenia gravis is an immune-mediated disorder caused by circulating autoantibodies against skeletal muscle acetylcholine receptors (Fig. 15-33). Binding of these antibodies to the acetylcholine receptor on the postsynaptic membrane leads to a severe decrease in the number of functional receptors. The mechanisms by which antibodies damage these receptors are (1) direct damage to the neuromuscular junction, which may be visible with electron microscopy as simplification of the membrane, and (2) formation of cross-linked antibodies leading to receptor internalization. Sufficient functional acetylcholine receptors are present to allow initially normal neuromuscular transmission, but the decrease in the number of available receptors leads to progressive weakness and collapse. Therefore acquired myasthenia gravis results in episodic collapse, and repetitive nerve stimulation causes a characteristic rapid decrease in amplitude of the muscle compound motor action potential. Diagnosis of myasthenia gravis can also be made following intravenous injection of cholinesterase inhibitors such as edrophonium chloride (Tensilon, ICN Pharmaceuticals, Costa Mesa, Calif) to collapsed animals. The reduction in cholinesterase activity leads to more available active acetylcholine within the synapse and rapid, although transient, restoration of skeletal muscle activity. Detection of circulating autoantibodies to acetylcholine receptors confirms the diagnosis.

Fig. 15-33 Schematic diagram of the pathogenesis of acquired (autoimmune) myasthenia gravis. (Modified from Kierszenbaum AL: *Histology and cell biology: an introduction to pathology*, St Louis, 2002, Mosby.)

The origin of the autoantibodies causing myasthenia gravis is not always known, but there is a strong link between thymic abnormalities and development of myasthenia gravis in both human beings and animals. Specialized cells within the thymic medulla, known as myoid cells, express skeletal muscle proteins, including those of the acetylcholine receptor. It is thought that these cells participate in development of self-tolerance. Abnormalities of the thymus, most commonly thymoma in animals and thymic follicular hyperplasia in human beings, can lead to loss of self-tolerance to acetylcholine receptors. In such cases, removal of the abnormal thymus can result in restoration of normal neuromuscular junction activity. When thymic abnormalities are not present, treatment with long-acting anticholinesterase agents and in some cases immunosuppressive agents, such as corticosteroids, is necessary.

1005

Congenital myasthenia gravis is an inherited disorder that is much less common than acquired myasthenia gravis. To date it has been described only in human beings, dogs, and cats. Animals with congenital myasthenia gravis are born with defective neuromuscular junctions that often have a decreased membrane surface area, best visualized with electron microscopy, and inherently reduced acetylcholine receptor density. Such animals may be normal at birth because there are sufficient functional acetylcholine receptors to support muscle contraction in a neonate. But with rapid postnatal growth, clinical signs of profound, sustained, and progressive weakness occur as a consequence of insufficient functional receptors to support the function of growing muscles.

1006

### 15.2.1.5.2.2

#### Botulism

Botulism is a neuromuscular disorder caused by the exotoxin of the bacterium *Clostridium botulinum*. Botulinum toxin is considered one of the deadliest of the known toxins. Botulism is characterized by profound generalized flaccid paralysis. Seven serologically distinct but structurally similar forms of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

botulinum toxin are designated A, B, C, D, E, F, and G. Sensitivity to these toxin types varies among different species. Dogs are most sensitive to type C toxin, ruminants to types C and D, and horses to types B and C.

Botulinum toxin occurs as a light chain and a heavy chain linked by a disulfide bond. Binding of botulinum toxin to receptors on the presynaptic terminals of peripheral nerves leads to toxin endocytosis. Within the endocytotic vesicle of the terminal nerve, the disulfide bond is cleaved, and the released light chain is translocated into the axonal cytoplasm. Botulinum toxin light chains are metalloproteinases. Numerous proteins are involved in the release of acetylcholine from presynaptic vesicles, and botulinum toxin blocks release of acetylcholine by irreversible enzymatic cleavage of one or more of these proteins. Different forms of botulinum toxin affect different proteins, but the end result is the same. Active neuromuscular junctions are the most sensitive, which has led to use of low levels of injected botulinum toxin as a treatment for localized muscular disorders resulting in spasm.

*Clostridium botulinum* spores are commonly present in the gastrointestinal tract of animals and in the soil. Under favorable anaerobic and alkaline conditions, these spores become active, with resultant toxin production. Botulism can occur because of ingestion of preformed toxin, such as in feed contaminated by dead rodents or soil-borne organisms, or from toxin produced by *Clostridium botulinum* organisms within the gastrointestinal tract or superficial wounds (Box 15-9). Dogs and cats, species that are most likely to ingest dead rodents containing botulinum toxin, are quite resistant to developing botulism. In veterinary medicine, horses are the most sensitive to botulinum toxin. Death of horses, most often due to respiratory muscle paralysis, can result from exposure to only very small amounts of botulinum toxin. The damage to presynaptic axon terminals is irreversible, and recovery from botulism occurs only following terminal axon sprouting and reestablishment of new functioning synapses.

15.2.1.5.2.2.1

### Box 15-9 Portals of Entry—Equine Botulism

Gastrointestinal colonization: Foals up to 6 months of age

Ingestion of preformed toxin: Adults, usually from rodent carcasses in hay or concentrated feed, or environmental contamination

Wound contamination: Adults, deep wounds, uncommon

15.2.1.5.2.3

### Tick paralysis

*Dermacentor* and *Ixodes* ticks can elaborate a toxin that also blocks release of acetylcholine from axon terminals. Tick paralysis is seen most often in dogs and children. Recovery following tick removal can be rapid (within 24 to 48 hours), indicating that the mechanism of toxin action in tick paralysis does not result in irreversible presynaptic damage and thus is different from that of botulinum toxin.

15.2.1.6

### NEOPLASIA

Neoplasms involving skeletal muscle are most often those that arise within the muscle or its supporting structures or that invade muscle from adjacent tissue.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

15.2.1.6.1

### Primary Muscle Tumors

Tumors with striated muscle differentiation are thought to arise from intramuscular pluripotential stem cells rather than from satellite cells. These tumors are uncommon and are either benign (rhabdomyoma) or malignant (rhabdomyosarcoma). Primary intramuscular tumors can also arise from fibrous tissue, vasculature, or neural elements. The most common tumor to arise from muscle-supporting structures is hemangiosarcoma.

15.2.1.6.1.1

### Rhabdomyoma and rhabdomyosarcoma

Tumors of striated muscle that occur at sites other than within muscle are rhabdomyomas of the heart or lung and botryoid rhabdomyosarcomas of the urinary bladder; these are not discussed in this section. Rhabdomyoma and rhabdomyosarcoma arising within skeletal muscle are most common in the dog, followed by the horse and cat. Morphologic variants include round cell, spindle cell, and mixed round and spindle cell, reflecting the developmental stages of skeletal muscle. Historically, diagnosis of tumors of skeletal muscle has relied on identification of cross striations indicative of sarcomeric differentiation. Cross striations are most often seen in elongated multinucleate cells known as “strap cells” (Fig. 34, C) and in ovoid cells known as “racquet cells.” They are most easily recognized following staining with phosphotungstic acid hematoxylin (PTAH) stain, but the search for cross striations can be extremely frustrating and unrewarding. These days the diagnosis of tumors of skeletal muscle origin relies primarily on results of immunohistochemical examination using antibodies for muscle-specific proteins. Muscle actin and desmin are expressed by smooth and skeletal muscle tumors, but myoglobin and sarcomeric actin are specific for skeletal muscle. Evidence of muscle differentiation, such as primitive myofilaments and Z-band structures, can also be seen by electron microscopy.

1006

1007

Rhabdomyoma is most often a round cell tumor and occurs most commonly in the larynx of adult dogs. The youngest reported age is 2 years. Tumors are generally smooth and nodular, pink, and unencapsulated. Histologic features are closely packed plump round cells that have central euchromatic nuclei, generally with a single prominent nucleus, and abundant vacuolated to granular eosinophilic cytoplasm. A small number of multinucleate and elongate strap cells can also be seen. Mitoses are rare, and evidence of invasion is uncommon.

Similar to the situation in human beings, rhabdomyosarcomas in animals most often occur at a young age and are most common in the neck or oral cavity, especially in the tongue. These tumors are pink and fleshy, and they often exhibit prominent local invasion. The most common and most distinctive form of rhabdomyosarcoma in animals is embryonal rhabdomyosarcoma, composed of primitive round cells with prominent euchromatic nuclei, a single prominent nucleolus, and either indistinct or prominent eosinophilic cytoplasm (“rhabdomyoblasts”; Fig. 15-34, A and B). Rhabdomyosarcoma can also contain elongate multinucleate strap cells (Fig. 15-34, C) and ovoid racquet cells. Cellular and nuclear pleomorphism is common, as is mitotic activity. These tumors are locally invasive and frequently metastasize, although too few cases have been studied to document any pattern of metastasis.

15.2.1.6.1.2

### Hemangiosarcoma

Malignant vascular neoplasms (hemangiosarcoma) arising within muscle are most common in the horse and dog ([Fig. 15-35](#)). Clinical signs include swelling within muscle, often with associated lameness. Cytologic preparations frequently reveal only peripheral blood, suggestive of a hematoma. Pathologic diagnosis can be difficult if multiple sites within the lesion are not sampled, as the amount of hemorrhage often far exceeds the area composed of proliferating neoplastic endothelial cells. Intramuscular hemangiosarcoma has a high incidence of metastasis, often to the lungs.

Fig. 15-34 **Rhabdomyosarcoma.** **A**, Skeletal muscle, cat. An admixture of small round basophilic cells with a lesser number of larger round cells with prominent eosinophilic cytoplasm is characteristic of embryonal rhabdomyosarcoma. Nuclei are central and euchromatic, most often with a single large nucleolus. H&E stain. **B**, Immunostaining reaction of the same rhabdomyosarcoma as depicted in [Fig. 15-34, A](#) showing intense cytoplasmic expression of desmin in many tumor cells, indicative of muscle origin (skeletal, cardiac, or smooth). These cells also express myoglobin and sarcomeric actin (not shown), which differentiates skeletal muscle tumors from smooth muscle tumors. Immunoperoxidase reaction for desmin. **C**, Botryoid rhabdomyosarcoma, urinary bladder, large breed dog. Cross striations, characteristic of a well-differentiated rhabdomyosarcoma, are present in the elongated multinucleate tumor cells. H&E stain. 1007

**Fig. 15-35 Intramuscular hemangiosarcoma, cervical skeletal muscle, horse.** Multiple irregular zones of cavitated (*upper right*) to solid tumor with hemorrhage have replaced normal muscle. Formalin fixed specimen. (Courtesy Dr. A. de Lahunta, College of Veterinary Medicine, Cornell University.)

### 15.2.1.6.2

#### Other Tumors Involving Skeletal Muscle

A variant of lipoma, known as infiltrative lipoma, often involves skeletal muscle. Characteristic gross pathologic and histopathologic findings are mature adipocytes invading skeletal muscle. This tumor is most common in the dog but has also been reported in young horses. Wide excision is the treatment of choice because this tumor will recur as a result of local invasion, but it does not metastasize.

Infiltration of skeletal muscle by neoplastic lymphocytes is not uncommon. Neoplastic lymphocytic infiltrates surround myofibers and can cause myofiber atrophy. These cells do not invade myofibers, however, and myonecrosis is rare. This helps to distinguish intramuscular lymphoma from lymphocytic myositis. Careful examination of infiltrating neoplastic cells typically reveals a relatively monomorphic population of lymphocytes, which may be atypical in appearance. Immunohistochemistry to confirm a single infiltrating cell type is also useful.

Vaccine-associated sarcoma in the muscle of the cat can arise within an intramuscular vaccination site or extend into underlying skeletal muscle from a subcutaneous injection site. Occasionally, mast cell tumors and carcinomas will exhibit prominent skeletal muscle invasion. Melanoma arising in the skin of older gray horses often metastasizes to muscle fascia and may exhibit some extension into the muscle itself. Intramuscular metastasis of tumors is rare (see Defense Mechanisms). Intramuscular metastasis of carcinoma, particularly prostatic, can occur in dogs. When carcinomas associated with sclerosis involve

## Pathologic Basis of Veterinary Disease, 4th Edition

---

muscle, either by extension or by metastasis, the muscle basement membrane is typically destroyed, often resulting in bizarre multinucleate cells representing attempts at muscle regeneration (Fig. 15-20). These bizarre cells should not be misidentified as tumor cells.

### 15.2.2 MUSCULAR DISORDERS OF DOMESTIC ANIMALS

Adequate muscle function is essential for the survival of any species. Many domestic animals have been selectively bred for improved musculature for meat production, performance, or appearance. Therefore muscle disease in animals can have a significant economic impact. In some cases, it is selection pressure imposed by human beings that has resulted in development and perpetuation of various myopathic conditions in animals. It is likely that continued selection pressures will lead to new mutations in the future.

It is interesting to compare the effects of muscular disorders that affect human beings and animals. The four-footed stance of animals allows for greater stability, which can allow an animal to remain ambulatory for some time, whereas a similarly affected person would be confined to a wheelchair. However, disorders that result in recumbency, even if it is transitory, can be devastating in livestock. It is much more difficult to nurse a large animal through a period of recumbency than it would be for a hospitalized human being or small animal patient.

The most common and important muscle disorders of animals are discussed by species because this is the way diseases are considered clinically. The same disease may occur in different species. Details of less common muscle disorders are presented in [Appendix 15-1](#).

#### 15.2.2.1 MUSCULAR DISORDERS OF THE HORSE

There is perhaps no other domestic animal species for which optimal muscle development and function is so critical as the horse. Selective breeding for better muscling has occurred in virtually all horse and pony breeds. The ability of such selection pressure to result in equine muscle mutations is exemplified by the relatively recent occurrence of hyperkalemic periodic paralysis (HYPP), in which a muscle mutation results in visually appealing increased muscle bulk and definition. Unfortunately, as you will see in the discussion of HYPP later, such mutations do not often result in improved muscle function.

##### 15.2.2.1.1 Bacterial and Parasitic Myopathies

Infection by various bacterial organisms and clostridial toxins can cause myopathy in the horse. Protozoa (*Sarcocystis* spp.) are common incidental findings in equine muscle, but protozoal myopathy is rare.

1008

##### 15.2.2.1.1.1 Clostridial myositis (malignant edema; gas gangrene)

1009

Clostridial myositis in the horse is an often fatal disorder caused by infection by various toxin-producing clostridial species, which are large gram-positive anaerobic bacilli. *Clostridium septicum* is the most common cause of clostridial myositis in horses, but *Clostridium perfringens* types A to E, *Clostridium chauvoei*, *Clostridium novyi*, and *Clostridium fallax* can also cause infection. Infection can involve more than one clostridial species. *Clostridium* spp. are ubiquitous organisms that form spores within the soil and within the gastrointestinal tract. Unlike cattle, in which nonpenetrating trauma causes muscle bruising and anaerobic conditions that activate clostridial spores already in the muscle, clostridial myositis in horses is virtually always secondary to a penetrating wound. Most often this is an injection site of a nonantibiotic substance, but infection of sites of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

puncture wounds and perivascular leakage of irritants in intravenously administered compounds are also possible. It is also possible that clostridial bacteria from the gastrointestinal tract can colonize damaged muscle. This is one possible explanation for the frequent occurrence of signs of colic before development of clostridial myositis at sites of injection of medications such as flunixin meglumine. Under anaerobic conditions, clostridia proliferate and produce toxins that damage blood vessels, resulting in hemorrhage and edema, and cause necrosis of adjacent muscle fibers (Table 15-4).

Clinical signs are acute onset of heat, swelling, and pain within a muscle group and adjacent fascia, with concurrent fever, depression, dehydration, and anorexia. If sufficient muscle necrosis is present, serum CK and AST concentrations may be mildly to moderately increased. Death from toxemia and/or septicemia often occurs within 48 hours. Affected muscle and adjacent fascia are swollen and often hemorrhagic, with edema, suppurative inflammation, and necrosis; gas may also be present (Fig. 15-36). Vasculitis is not seen. Gram-positive bacilli characteristic of *Clostridium* spp. are generally demonstrable within affected tissue.

The diagnosis can be made with reasonable certainty based on typical historical, gross pathologic, cytologic, and histopathologic findings. *Clostridium* spp. can also be identified by culture under anaerobic conditions or by a fluorescent antibody test. Treatment must be initiated rapidly and includes surgical incisions into affected muscle to allow drainage and oxygenation, antibiotic therapy, and supportive care.

15.2.2.1.1.2

### Botulism

Technically this disease is a neuromuscular junction disorder and is included in this section for convenience. Botulism is caused by *Clostridium botulinum* toxin and is often not associated with *Clostridium botulinum* infection. The portals of entry of botulinum toxin in horses are summarized in Box 15-9. *Clostridium botulinum* bacteria are found as spores within the gastrointestinal tract of many mammals, and spores are common in the soil. Preformed toxin within contaminated feed or soil is the most common cause of botulism in adult horses. However, in foals, usually between 1 week and 6 months of age, ingestion of *Clostridium botulinum* spores can lead to proliferation of toxin-producing *Clostridium botulinum* within the intestinal tract, resulting in toxicoinfectious botulism (shaker foals). Wound infection is an uncommon cause of botulism in horses.

Fig. 15-36 **Clostridial myositis, malignant edema, horse.** **A,** *Clostridium septicum* is the most common cause of clostridial myositis in horses. Affected muscle (*shown here*) and adjacent fascia (*not shown here*) are swollen and often hemorrhagic. **B,** Interstitial edema, hemorrhage, and inflammatory cells surround numerous swollen and fragmented necrotic myofibers. Formalin fixation, H&E stain. (**A,** Courtesy College of Veterinary Medicine, Cornell University. **B,** Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

The pathogenesis of botulism has been previously discussed (see Neuropathic and Neuromuscular Junction Disorders). Irreversible binding of toxin to presynaptic nerve terminals and blockage of acetylcholine release lead to the profound generalized flaccid paralysis that is the hallmark of botulism. Clinical signs are acute and progress rapidly, generally resulting in recumbency. Dysphagia and tongue weakness are common findings that help to distinguish botulism from other neuromuscular diseases causing recumbency. Serum concentrations of CK and AST are within normal limits (indicating the absence of damage to myofibers) or are possibly slightly increased as a result of ischemic myopathy secondary to recumbency (see later discussion).

1009

1010

No specific gross or histopathologic lesions are present in horses dying with botulism, although aspiration pneumonia caused by dysphagia can occur. Muscle fibers are intact unless recumbency has compromised their blood supply, causing ischemia and localized myofiber necrosis.

Evaluation of stomach contents or contaminated feed may reveal the presence of toxin. However, horses are exquisitely sensitive to botulinum toxin, and as only a small concentration of the toxin may be present in an affected horse, available tests may not detect such a low concentration of toxin. In most equine cases, the diagnosis is made based on the clinical history after elimination of other possible causes of profound muscular weakness. Affected animals should be treated with polyvalent botulinum antitoxin to prevent further binding of toxin. Recovery occurs following terminal axon sprouting and reestablishment of functional neuromuscular junctions. Vaccination with botulinum toxoid is an effective preventive measure.

15.2.2.1.1.3

### *Corynebacterium pseudotuberculosis* (pigeon fever)

Intramuscular abscesses due to *Corynebacterium pseudotuberculosis* occur almost exclusively in horses in arid regions of the Western United States and Brazil. *Corynebacterium pseudotuberculosis* is a gram-positive pleomorphic facultative anaerobic bacillus present within the soil. It can enter muscle via penetrating wounds, including injection sites. The biotype most common in horses is different from that which affects sheep and goats as it is unable to reduce nitrates to nitrites. The high lipid content of the bacterial cell wall contributes to survival within macrophages, and bacterial exotoxins, such as phospholipase D, contribute to vascular damage and inhibition of neutrophil function. Equine infections occur most frequently during the fall and early winter, and a higher incidence of the disease is often seen following rainy winters. Infections are most common in the pectoral muscles, but other locations are possible. Affected muscles are swollen and edematous, and contain variably sized zones of localized suppurative inflammation. Fever is common. The causative agent is readily isolated from affected tissue and can be seen in aspirates from intramuscular abscesses. Treatment is generally curative and includes antibiotic therapy and establishment of drainage of abscesses. Rarely, infection with *Corynebacterium pseudotuberculosis* in horses leads to immune-mediated vasculitis (purpura hemorrhagica; see next discussion).

15.2.2.1.1.4

### Streptococcal-associated myopathies

Two distinct degenerative myopathies are associated with infection or exposure of the horse to *Streptococcus equi* ssp. *equi*. One, known as purpura hemorrhagica, has been recognized for many years. The other, known as streptococcal-associated rhabdomyolysis and muscle atrophy, has only recently been recognized.

## Pathologic Basis of Veterinary Disease, 4th Edition

15.2.2.1.1.4.1

### Purpura hemorrhagica.

In this disease, muscle damage is not caused by the direct infection of the muscles but rather by an immune response to the bacterial pathogen. *Streptococcus equi* is the most common cause of purpura hemorrhagica in horses, but other bacteria can also be involved. In cases caused by *Streptococcus equi*, circulating immune complexes composed of immunoglobulin A (IgA) antibodies and streptococcal M antigen deposit in small vessels. This leads to vasculitis and vascular wall necrosis (Fig. 15-37), with resultant hemorrhage and infarction of myofibers. It is also possible that antibodies to streptococcal M protein cross-react with skeletal and cardiac muscle myosins to cause direct injury.

Signs of myopathy often accompany systemic signs of poststreptococcal purpura in horses (i.e., depression, fever, dependent edema, petechiae or ecchymoses, leukocytosis, increased serum fibrinogen, and anemia), but myopathy can also be the primary presenting disease process. Affected horses are weak, may have a short-strided gait, and can become recumbent.

Myoglobinuria and very high increases in serum concentrations of CK and AST are common.

1010

1011

**Fig. 15-37 Intramuscular vasculitis, purpura hemorrhagica, skeletal muscle, transverse section, horse.** In the wall of the blood vessel (*upper left*) is a band of circumferential fibrinoid necrosis containing nuclear debris. Many of the adjacent myofibers are necrotic. Some of these myofibers are fragmented, and a small number contain fine basophilic deposits of mineral. Formalin fixation, H&E stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Multiple muscles are involved (as opposed to the locally extensive lesion of clostridial myositis), and affected muscles contain multifocal to locally extensive hemorrhage and edema that dissects between necrotic muscle fibers. Gross pathologic findings are similar to those seen in clostridial myositis (Fig. 15-36, A), but lesions do not contain gas bubbles. Vasculitis (Fig. 15-37) is present on microscopic examination and is the diagnostic feature.

Diagnosis is based on a history of exposure of the horse to *Streptococcus equi* and typical clinical, clinicopathologic, and histopathologic findings. Because this is an immune-complex disorder, histopathology, cytology, and bacterial cultures of affected muscle do not reveal *S. equi*. This organism or other causative organisms may be cultured from other affected tissues, especially lymph nodes or guttural pouch. A high serum titer to *Streptococcus equi* M protein is strongly supportive of streptococcal-associated purpura hemorrhagica. Treatment includes corticosteroid therapy and supportive care, but horses frequently succumb to other manifestations of systemic vasculitis, such as gastrointestinal infarcts.

15.2.2.1.1.4.2

### Streptococcal-associated rhabdomyolysis and muscle atrophy.

A syndrome of severe acute rhabdomyolysis and profound rapidly progressive generalized muscle atrophy has also been seen in horses infected or even just exposed to *Streptococcus equi*. This syndrome occurs most frequently in young to young adult quarter horses, but young horses of other breeds can also be affected. Clinically recognized muscle atrophy is often most evident in paraspinal and gluteal muscles. Some cases have microscopic evidence of concurrent polysaccharide storage myopathy (see Inherited or Congenital Myopathies), which may be a predisposing factor. In others, nonsuppurative perivascular and interstitial inflammation has been detected, and immune-mediated damage caused by cross reaction of streptococcal antibodies with muscle proteins has been proposed. Affected horses do not show typical signs of purpura hemorrhagica but often have very high serum concentrations of CK and AST. Affected horses may respond to corticosteroid therapy. Most will recover, but recurrence following subsequent *Streptococcus equi* exposure is possible.

15.2.2.1.1.5

### Protozoal myopathy

Protozoa (*Sarcocystis* spp.) are common incidental findings in equine skeletal and cardiac muscle. As the protozoa are in cysts within the myofiber itself and thus are protected from the body's surveillance, there is no inflammatory response. Massive infection by *Sarcocystis fayeri* is suspected of causing a degenerative myopathy in horses, but this is rare. Rarely, localized thickening of the tongue has been found in horses with granulomatous myositis, the result of sarcocystis organisms within tongue musculature.

15.2.2.1.1.6

### Ear tick-associated muscle spasms

Episodic muscle spasms can occur in horses with ear ticks (*Otobius megnini*). The mechanism is not known. Dimpling of affected muscles following percussion can be seen, but myotonic discharges are not found with electromyography. Treatment for ear ticks results in rapid recovery.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.1.2 Nutritional and Toxic Myopathies

Nutritional deficiency, most often of selenium, and various toxins are relatively common causes of degenerative myopathy in the horse.

#### 15.2.2.1.2.1 Nutritional myopathy

Foals (most commonly up to 2 weeks of age) and young adult horses are most susceptible to nutritional myopathy because of a deficiency of the antioxidants selenium or (less commonly) vitamin E. In severely selenium-deficient areas, such as the Pacific Northwest, selenium deficiency myopathy can occur in horses of any age. Selenium present in the soil is taken up by growing plants. In many areas, the soil is selenium deficient, and selenium supplements to the animal's ration must be provided. Vitamin E deficiency occurs in horses that eat marginal- to poor-quality grass hay and have little or no access to pasture and no supplemental vitamin E. Oxidative injury to actively contracting muscle fibers occurs as a result of a lack of antioxidant activity.

Affected foals are most likely to be those born to selenium-deficient mares. Foals have generalized weakness, which may be present at birth or become apparent soon after birth. Affected foals may become recumbent but are generally bright and alert. They often continue to suckle if bottle fed, but weakness of the tongue and pharyngeal muscles can lead to weak suckling.

Affected adult horses are most often stabled horses fed only selenium-deficient hay, with clinical disease being seen most commonly in the late winter or early spring. In the Pacific Northwest, selenium deficiency myopathy can occur in adult horses fed only pasture or hay, and it can occur at any time of year. Affected adult horses often show preferential involvement of the temporal and masseter muscles (sometimes inappropriately termed maxillary myositis or masseter myositis) with swelling and stiffness of these muscles and impaired mastication. Involvement of pharyngeal muscle results in dysphagia, which can be mistaken for botulism. In more chronic cases, bilaterally symmetric atrophy of the masseter muscles may be evident, which can be mistaken for atrophy secondary to protozoal myeloencephalitis. Careful examination of these horses often reveals generalized weakness, evident as a stiff, short-strided gait. Severely affected horses can have an acute onset of recumbency that mimics neurologic disease. 1011 1012

Serum concentrations of CK and AST are generally mildly to moderately increased, although extremely high concentrations can be seen in severely affected foals and horses. Concentric needle electromyography of affected muscles results in abnormal spontaneous activity (positive sharp waves, fibrillations, and myotonic bursts).

Muscles of affected horses appear pale (hence the common name *white muscle disease*), often in a patchy distribution (Fig. 15-44). The most severely affected muscles are those that have the highest workload (e.g., cervical muscles, proximal limb muscles, tongue, and masticatory muscles). The gross appearance depends on the extent of the necrosis and the stage. In early stages, yellow and white streaks are present, and later pale, chalk white streaks often appear. Horses with impaired swallowing can have cranioventral aspiration pneumonia. Severely selenium-deficient foals and horses will also have pale areas of necrosis within the myocardium, especially the left ventricular wall and septum. The stage of the necrosis depends on the age of the lesions. In foals with severe, acute myopathy leading to death or euthanasia, lesions are at the stage of massive muscle necrosis and mineralization

## Pathologic Basis of Veterinary Disease, 4th Edition

---

with minimal macrophage infiltration (monophasic). In animals that have lived longer (i.e., subacute cases), the lesions are polyphasic, and active necrosis, macrophage infiltration, and regeneration are present. Although type 1 fibers may be more likely to develop necrosis because of nutritional myopathy, in severely affected muscles almost all fiber types are affected. In cases with myocardial involvement, myocardiocyte necrosis and mineralization are present. If the animal survives, the necrotic myocardiocytes are replaced by fibrovascular connective tissue that forms a scar.

Diagnosis of nutritional myopathy is based on typical history, increases in serum concentrations of CK and AST, deficient blood concentrations of selenium or vitamin E, and characteristic gross and histopathologic findings. If horses live long enough, myofiber regeneration can restore the muscles to normal. This disorder in foals can be prevented by supplementing the ration of mares with selenium during gestation. Foals born in selenium-deficient areas can also be given injectable vitamin E and selenium soon after birth. Young adult horses should be given sufficient dietary vitamin E and selenium. Treatment with selenium and vitamin E after the onset of clinical signs is far less effective than prevention.

### 15.2.2.1.2.2

#### Ionophore toxicity

The pathogenesis of ionophore toxicity is discussed in the section titled Toxic Myopathies. Horses are exquisitely sensitive to ionophores and will succumb to very small doses. Ionophores may be present as contaminants within horse feed, or the horse may be accidentally fed ionophore-containing feeds intended for other domestic animals.

Most of the available literature relates to monensin toxicity, but the effects of other ionophores should be similar. In acute monensin toxicity, death occurs because of shock and cardiovascular collapse, and no specific lesions are seen on postmortem examination within the first 48 hours. If the horse survives 3 to 4 days, cardiac muscle necrosis and segmental necrosis of skeletal muscle occurs (Fig. 15-38, B, Fig. 15-16, B), with concurrent increases in serum concentrations of CK and AST, which may be severe. Affected skeletal and cardiac muscles will often contain pale streaks (Fig. 15-38, A). Given the profound sensitivity of horses to ionophores, ionophore toxicity in horses is typically the result of a single dose and thus the lesion is a monophasic multifocal process. This helps to differentiate ionophore toxicity from nutritional myopathy, which is often polyphasic. Both type 1 and type 2 fibers are affected. If the horse survives, necrosis is followed by myofiber regeneration, which can restore the muscles to normal. Necrotic myocardiocytes will be replaced by fibrosis because of the lack of significant regeneration of the myocardium. Horses dying at 14 days postionophore exposure often have normal skeletal muscles and extensive myocardial fibrosis. Acute cardiac failure and death because of myocardial scarring can occur months to years following apparent recovery from ionophore exposure.

Diagnosis is based on a history that includes both ingestion of ionophores and the presence of the characteristic gross or histopathologic findings. Analysis of feed or stomach contents for ionophores is definitive. Treatment for ionophore-intoxicated horses is supportive, as there is no specific therapy.

### 15.2.2.1.2.3

#### Plant toxicities

A number of toxic plants are known to cause muscle necrosis in horses (see also Toxic Myopathies). These include *Cassia occidentalis* (coffee senna) and *Thermopsis* spp. Most plant-associated toxicities in horses are associated with plants growing in pastures or baled into hay. Necrosis is most often

## Pathologic Basis of Veterinary Disease, 4th Edition

---

polyphasic. Cardiac myonecrosis may or may not also be present. In the United Kingdom, a syndrome of pasture-associated myonecrosis has been documented in horses for which the cause is as yet unknown.

### 15.2.2.1.3 Inherited or Congenital Myopathies and Myotonic Disorders

#### 15.2.2.1.3.1 Hyperkalemic periodic paralysis (HYPP)

This myotonic disorder affects horses whose ancestry traces back to a quarter horse stallion named *1012*  
Impressive. Affected horses generally have remarkably well-defined muscle groups, which has lead to *1013*  
their popularity for showing in halter. The disease is inherited as an autosomal dominant disease.  
Therefore affected horses can be either heterozygotes or homozygotes. Homozygous foals often have  
a distinctive laryngeal muscle dysfunction that results in laryngospasm and labored breathing, and  
most homozygous horses are considered nonviable.

**Fig. 15-38 Ionophore toxicity, monensin, skeletal muscle. A,** Necrosis. The pale white to gray foci are areas of necrotic myofibers. Myocardium will often contain similar lesions. **B,** Segmental myofiber necrosis (2 days old), longitudinal section, horse. The segment of myofiber visible here is necrotic, fragmented, and infiltrated by macrophages and neutrophils. Note the intact basal lamina and endomysium on both sides of the myofiber, which will contain the regenerating myofiber and thus facilitate resolution. Ionophore toxicity results in calcium overload and death of skeletal (also cardiac) myocytes. Formalin fixation, H&E stain. (**A**, Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The underlying defect in HYPP is a point mutation in the gene encoding the  $\alpha$  subunit of the skeletal muscle sodium channel. This defect causes abnormal (delayed) inactivation of sodium channel activity, resulting in membrane instability and continuous muscle fiber electrical activity, which is reflected in EMG findings (see later discussion). The pathogenesis of clinical signs of HYPP is complex and not entirely understood, either in horses or in human beings with a similar disorder. Affected heterozygotes have a mosaic of abnormal and normal sodium channels, and resting muscle membrane potentials are typically lower than normal. This leads to an increased likelihood of electrical generation of a prolonged muscle action potential, resulting in transient myotonia. When abnormal sodium channels are activated, the response to the abnormally increased intracellular sodium is release of potassium to the extracellular space and blood stream, resulting in hyperkalemia. Hyperkalemia is not, however, a consistent finding. Feeding of high potassium feeds, such as alfalfa products or feeds with added molasses, can precipitate clinical signs of HYPP, possibly by activating abnormal sodium channels. Another potential consequence of prolonged activation of abnormal sodium channels is inactivation of normal sodium channels, resulting in flaccid paralysis and collapse. This result would explain the typical signs seen during episodes, which include transient muscle spasm (myotonia), with protrusion of the third eyelid, followed by flaccid paralysis. Decreased muscle temperature, as can occur as a result of a chilling rain, can precipitate episodic collapse in HYPP horses, possibly by decreasing the activity of the muscle sodium-potassium exchanger (the Na-K ATPase), an important means by which affected muscle compensates for abnormal sodium channel activity. Postanesthetic recumbency and anesthesia-associated hyperthermia have also been seen in HYPP horses. Affected horses can appear normal for many years, can have multiple episodes of collapse, or can die acutely. Serum concentrations of CK and AST are generally normal. Abnormal ionic fluxes occur at all times in affected horses, and concentric needle electromyography between paralytic episodes reveals characteristic persistent myotonic bursts.

There are no gross pathologic findings in HYPP horses other than prominent muscling. Affected skeletal muscle is generally histologically normal, although scattered intracytoplasmic vacuoles (vacuolar myopathy) can be present in type 2 fibers. The characteristic pathologic finding of HYPP is only evident at the ultrastructural level, where dilated terminal cisternae of the sarcoplasmic reticulum are found.

Diagnosis can be made with reasonable certainty based on characteristic clinical signs and clinicopathologic findings in a horse of Impressive line breeding. Myotonic bursts with concentric needle electromyography are also diagnostic. The simplest and most reliable test, however, is a DNA-based test performed on peripheral white blood cells or, more recently, on cells obtained from the base of pulled mane or tail hairs. Treatment consists of feeding a low-potassium diet, which means avoiding alfalfa products and molasses. A low-potassium diet can be successful in controlling signs in many cases. More severe cases can be treated with the diuretic acetazolamide, which causes increased urinary excretion of potassium. Acute episodes can be treated by intravenous dextrose or insulin or with oral sugar solutions such as sugar syrup. Administration of glucose to stimulate insulin secretion, or of insulin itself, will aid in alleviating signs by helping to drive intracellular movement of potassium along with glucose.

1013

1014

### 15.2.2.1.3.2

#### Polysaccharide storage myopathy

This myopathy, designated with the acronyms EPSM, PSSM, or EPSSM, is most commonly recognized in quarter horse, warm blood, Arabian, Morgan, pony of the Americas, and draft-related breeds. It also occurs in many other horse and pony breeds, including miniature horses. Survey

## Pathologic Basis of Veterinary Disease, 4th Edition

---

examination of equine muscle samples has revealed an astonishing incidence of approximately 66% in all draft-related horses and approximately 30% in all light horses. Not all affected horses exhibit obvious clinical signs of muscle dysfunction. This disorder is thought to be inherited as an autosomal dominant trait, although the exact mode of inheritance is not clear at this time.

In contrast to other glycogenoses affecting skeletal muscle, to-date no abnormality in the glycolytic or glycogenolytic pathways in skeletal muscle has been identified, making this equine disorder unique, but an underlying carbohydrate metabolic disorder is still suspected. Affected horses appear to have a more rapid intramuscular uptake of blood glucose than controls, although the exact mechanism for this phenomenon is still unknown. Abnormal accumulation of intracytoplasmic glycogen (confirmed by being PAS-positive, amylase-sensitive) within type 2 fibers is the histologic finding. In severe cases, aggregates of abnormal glycogen are eventually ubiquitinated, resulting in amylase-resistant inclusions composed of glycogen and filamentous protein. Certain breeds, such as quarter horse and draft-related breeds, seem to be most prone to the development of amylase-resistant inclusions, whereas glycogen aggregates are more common in other breeds. The explanation for this difference is as yet unknown.

Clinical signs are variable, and all are thought to be caused by insufficient energy production by affected muscle fibers. Abnormal myofiber function due to architectural alteration secondary to deposition of complex polysaccharide is also possible, although the excellent response to therapy even in horses with severe intramyofiber inclusion accumulation suggests that this is less significant than is altered energy metabolism. Recurrent exertional rhabdomyolysis (see later discussion) is a commonly recognized sign, but unexplained pelvic limb lameness is even more common than clinical rhabdomyolysis. Affected horses can also have a stiff gait, symmetric muscle atrophy, back soreness, muscle cramping resulting in abnormal hindlimb flexion characteristic of shivers, and bilateral pelvic limb or generalized weakness. In draft horses, sudden onset of spontaneous recumbency or postanesthetic recumbency because of myopathy can occur. Serum concentrations of CK and AST are markedly increased after episodes of exertional rhabdomyolysis but may be only mildly to moderately increased in affected horses after exercise or onset of recumbency. Normal serum levels of CK and AST in affected horses are thought to indicate that the muscle dysfunction is not associated with overt myonecrosis. Concentric needle electromyography may reveal abnormal spontaneous activity (scattered positive sharp waves and fibrillations).

In severe cases, in which horses have died or been euthanatized because of rhabdomyolysis or recumbency, muscles may be pale pink or diffusely red-tinged, which can be mistaken for autolysis. Multifocal pale zones may be present (Fig. 15-40, A). In draft horses, chronic myopathy can result in overall reduction in muscle mass. Muscles in severely affected draft horses can also be of normal size but may contain pale streaks where myofibers have been replaced by fat. The most severely affected muscles are those of the proximal thigh and epaxial muscles of the back (e.g., longissimus), although any of the large “power” muscle groups, including pectoral and shoulder girdle muscles, can be affected. Swollen, dark kidneys (pigmentary nephrosis) caused by myoglobinuria can be seen in horses dying with severe rhabdomyolysis. The extent of overt myofiber necrosis is extremely variable; massive necrosis or regeneration can be seen after severe rhabdomyolysis, whereas only minimal scattered fiber necrosis may be seen in recumbent horses. Lesions are monophasic if there has been only a single bout of exertional rhabdomyolysis, or polyphasic if there have been repeated bouts of less severe exercise-induced injury. Fiber necrosis is uncommon in muscle biopsy samples taken from affected horses while they are clinically normal.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The characteristic histologic finding is aggregates of intracytoplasmic material that stain positively with PAS reaction for glycogen (Fig. 15-39, *A*). In severe cases, multiple pale intracytoplasmic inclusions will also be seen with H&E stain (Fig. 15-39, *B*). These inclusions are PAS-positive (Fig. 15-39, *C*) and resist digestion by amylase and are thus not glycogen. Terms used to describe this amylase-resistant material include amylopectin, polyglucosan, and complex polysaccharide. In chronic cases, myofibers also exhibit chronic myopathic change (atrophy, hypertrophy, internal nuclei), and fat replacement of myofibers can occur in severe cases.

1014

1015

**Fig. 15-39 Equine polysaccharide storage myopathy, semimembranosus muscle, transverse sections, horse. A,** Note the increased amount of and irregularly distributed dark-pink staining glycogen. Abnormal aggregates are present both beneath the sarcolemma and within the cytoplasm. Formalin fixation, PAS reaction. **B,** Severe form. Numerous myofibers contain multiple pale (*very light pink*) subsarcolemmal and intracytoplasmic inclusions of stored polysaccharide. Formalin fixation, H&E stain. **C,** These inclusions shown in [Fig. 15-39, B](#) stain intensely with PAS but are not digested by amylase (not shown) and are characteristic of what is called complex polysaccharide, amylopectin, or polyglucosan. Formalin fixation, PAS reaction. (**A, B, and C,** Courtesy Dr. B.J. Cooper, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

At this time, the diagnosis of polysaccharide storage myopathy depends on finding characteristic histopathologic changes in muscle samples of horses with appropriate clinical signs. Gluteal, semimembranosus, or semitendinosus muscle samples are preferred, although changes in longissimus muscle are also found, especially in horses with back pain. A presumptive diagnosis of polysaccharide storage myopathy can be made based on characteristic clinical findings in a predisposed breed. Treatment has relied on altering the diet to minimize starch and sugar intake (less than 15% of total daily calories) and maximize fat intake (at least 20% to 25% of total daily calories from fat). Grains and sweet feeds are replaced by high-fiber, low-starch, low-sugar feeds, with added fat in the form of vegetable oil, powdered fat, or high-fat rice bran supplements. Provision of as much time in a pasture or paddock and regular exercise as possible are also important. Treatment is very successful in most cases.

15.2.2.1.3.3

### Glycogen brancher enzyme deficiency (glycogenosis type IV)

This disorder is due to a congenital lack of a glycogenic enzyme, glycogen brancher enzyme (GBE), and is an emerging disease in quarter horses and American paint horses. This disorder is inherited as an autosomal recessive trait. Affected foals may be aborted, stillborn, or weak at birth or can have contracted tendons, rhabdomyolysis, or cardiac failure at an early age. The consequence of GBE deficiency is the accumulation of long unbranched chains of glucose within cells that leads to abnormal glycogen formation and deposition. These molecules would normally be converted into glycogen in the presence of GBE in the final step in the formation of glycogen. There are no specific gross pathologic findings. Pulmonary edema may be found in foals that die from cardiac failure. Characteristic histologic findings are round hyaline inclusions resembling amylopectin (polyglucosan bodies) within skeletal and cardiac myocytes, especially Purkinje fibers, and to a lesser degree within hepatocytes. Inclusions are also common in the brain and spinal cord and, unlike glycogen, are PAS-positive and resistant to amylase digestion. As with other carbohydrate metabolic defects, a lack of energy production by affected fibers is thought to underlie cellular dysfunction. Disruption of cytoarchitecture due to amylopectin deposition may also contribute. Analysis of peripheral blood or skeletal muscle for GBE activity will identify affected animals with severely reduced GBE activity and carriers in which GBE activity is moderately reduced. A DNA test using pulled mane or tail hairs is now available to detect carriers and affected horses. There is no treatment for this disorder.

1015

15.2.2.1.3.4

### Myotonia and mitochondrial myopathy

A myotonic disorder occurs occasionally in horses, and a mitochondrial myopathy has been described in an Arabian horse. These disorders are discussed in more detail in [Appendix 15-1](#).

1016

15.2.2.1.4

### Other Equine Myopathies

15.2.2.1.4.1

### Exertional rhabdomyolysis

Equine exertional rhabdomyolysis (tying up, azoturia, Monday morning disease, setfast, blackwater) is characterized clinically by sudden onset of stiff gait, reluctance to move, swelling of affected muscle groups (especially gluteal), sweating, and other signs of pain and discomfort. Serum concentration of CK and AST are often markedly increased. Signs may appear during or immediately after exercise, but only rarely is exertional rhabdomyolysis associated with exhaustive exercise. In

## Pathologic Basis of Veterinary Disease, 4th Edition

---

severely affected horses, even minimal exercise such as walking out of a stall can cause clinical signs. An association with high grain feeding and lack of regular exercise has been recognized for many years. Previous theories regarding the pathogenesis of equine exertional rhabdomyolysis include development of muscle lactic acidosis, vitamin E and/or selenium deficiency, hypothyroidism, and electrolyte abnormalities. It is only recently that studies have concluded that lactic acidosis is not a finding in horses with exertional rhabdomyolysis, that hypothyroid horses show no signs of degenerative myopathy, and that electrolyte abnormalities as a primary cause of equine exertional rhabdomyolysis are rare. It is still thought that vitamin E or selenium deficiency can exacerbate signs of exertional rhabdomyolysis in predisposed horses, but neither vitamin E nor selenium deficiency is considered a primary cause. Recent studies have found that affected horses typically have an underlying myopathy, most often polysaccharide storage myopathy. There is some evidence to suggest that recurrent exertional rhabdomyolysis in thoroughbreds is because of abnormal calcium homeostasis within skeletal muscle, although other affected thoroughbreds have been found to have polysaccharide storage myopathy. As muscle necrosis per se is neither painful, nor does it cause muscle swelling, it is suspected that other factors play a role in this disorder in the horse. These factors include oxidative injury to muscle membranes occurring secondary to segmental necrosis and release of reactive compounds from damaged membranes, which may explain the perceived benefit of supplemental vitamin E and selenium to affected horses, and vascular injury, which results in ischemia (i.e., compartment syndrome).

Gross findings are similar to those described for polysaccharide storage myopathy ([Fig. 15-40, A](#)). Histologic findings are localized or widespread muscle fiber necrosis ([Fig. 15-40, B](#)) followed by the usual sequence of events, macrophage infiltration and regeneration. Affected fibers are primarily type 2 fibers. Lesions can be either monophasic or polyphasic.

Fig. 15-40 **Acute rhabdomyolysis, skeletal muscle, horse.** **A**, Affected muscles may be pale pink or diffusely red-tinged, which can be mistaken for autolysis. Multifocal pale zones may also be present. **B**, Segmental myofiber necrosis, semitendinosus muscle, transverse section. Most of the myocytes are necrotic and at the stage of coagulation necrosis. In a few myofibers, necrosis is at a later stage and the necrotic sarcoplasm has lysed, leaving empty sarcolemmal tubes. A couple of necrotic myofibers are at an even later stage and contain a small number of macrophages. Formalin fixation, H&E stain. (**A**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. B.J. Cooper, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Diagnosis is based on typical clinical signs and clinicopathologic evidence of muscle injury (increased activity of CK or AST). Treatment for an acute episode includes nonsteroidal antiinflammatory agents, acepromazine, and rest. Careful evaluation of the patient for evidence of renal damage ([pigmentary] myoglobinuric nephrosis) because of myoglobin released from damaged muscle is indicated. Long-term treatment and prevention include correction of any concurrent electrolyte, mineral, or vitamin deficiencies and most importantly a change in diet to one that is high in fat and fiber and low in starch and sugar, as described for horses with polysaccharide storage myopathy (see Inherited or Congenital Myopathies). Thoroughbreds with recurrent exertional rhabdomyolysis due to suspected underlying calcium handling abnormalities also respond well to this type of diet.

1016

1017

15.2.2.1.4.2

### Hyperthermia

Malignant hyperthermia occurring during general anesthesia and development of postanesthetic hyperthermia (sometimes called hypermetabolism to distinguish it from true malignant hyperthermia) occurs in horses. A genetic defect in the skeletal muscle ryanodine receptor, similar to malignant hyperthermia in human beings, dogs, and pigs, has been identified in some horses with malignant hyperthermia triggered by anesthetic agents. Some affected horses with a hyperthermia-like syndrome occurring during anesthesia or with hyperthermia occurring during recovery from anesthesia have HYPP or polysaccharide storage myopathy, but in some cases the exact cause of these conditions is not clear. It is likely that, similar to hyperthermia in human beings, a variety of underlying myopathies, especially those that result in uncoupling of mitochondria within skeletal myocytes (see Malignant Hyperthermia), can predispose animals to anesthesia-associated hyperthermia. Studies of muscle from horses with exertional rhabdomyolysis have detected loosely coupled mitochondria, which could predispose them to malignant hyperthermia-like episodes. The extent of overt muscle fiber necrosis due to hyperthermia varies but is often severe.

15.2.2.1.4.3

### Ischemic myopathy

In addition to vascular damage due to clostridial toxins or immune-mediated vasculitis, ischemic myopathy of pectoral and limb muscle can be seen in recumbent horses as the result of pressure interfering with vascular perfusion. Once the horse is moved or is standing, reperfusion injury can occur. Development of compartment syndrome can contribute to ischemic injury (see Disturbance of Circulation). Ischemic myopathy of the abdominal muscles can be seen after prolonged lifting of a horse with a sling. In these cases, affected muscles generally show degenerative or regenerative changes that are all at about the same stage (monophasic necrosis). Concurrent necrosis and regeneration (polyphasic necrosis) can also be seen in horses that are in a sling or recumbent for an extended period of time. Recovery will depend on the extent of injury and the ability to regenerate (i.e., depending on whether the basal lamina is intact and the extent of satellite cell injury and necrosis).

Transient pelvic limb muscle ischemia due to aortoiliac mural thrombosis occurs in horses. The cause of the thrombosis is unknown, although it has been attributed to migration of strongyle larvae. Typically the thrombus is not occlusive, and clinical signs of pelvic limb dysfunction occur only during or after strenuous exercise, such as racing. A short-strided gait and a decreased surface temperature of the distal portion of the affected limb during episodes are characteristic. Because the ischemia is transient, pathologic studies are few. But overt myofiber necrosis is thought to be minimal, and recovery is typically rapid.

15.2.2.1.4.4

### Postanesthetic myopathy

Degenerative myopathy can occur in horses undergoing prolonged recumbency during general anesthesia. In some cases, muscle damage may be due to ischemia from systemic hypotension leading to muscle hypoxia or from pressure caused by the weight of large muscle masses during recumbency, especially when adequate padding has not been provided. Underlying myopathy of various types will also predispose to postanesthetic myopathy. In ischemic damage, the location of the lesions depends on the position of the horse during anesthesia. In dorsal recumbency, the gluteal and the longissimus muscles are ischemic; in lateral recumbency, the triceps brachii, pectoralis, deltoideus, and brachiocephalicus muscles of the leg under the body become ischemic. The basic mechanism is that the pressure in the muscle exceeds the perfusion pressure in the capillaries. The use of adequate padding under the recumbent horse and the maintenance of normal blood pressure during anesthesia have greatly reduced the incidence of postanesthetic myopathy from muscle ischemia in horses. These days, underlying myopathy, particularly polysaccharide storage myopathy, appears to be the most common cause of postanesthetic myopathy in horses.

15.2.2.1.4.5

### Endocrine myopathies

Although hypothyroidism is often suggested to be a cause of muscle dysfunction in the horse, studies of experimentally thyroidectomized horses have failed to support hypothyroidism as a cause of equine myopathy. Pituitary hyperfunction due to adenoma or hyperplasia in older horses, causing equine Cushing's disease, is the most common equine endocrine disorder causing muscle atrophy and weakness. The characteristic pot-bellied appearance of affected horses is thought to be secondary to abdominal muscle weakness.

15.2.2.1.5

### Denervating Diseases

Localized or generalized muscle dysfunction can be caused by disorders affecting motor neurons or peripheral nerves. Several syndromes of peripheral nerve dysfunction are recognized in the horse.

1017

1018

15.2.2.1.5.1

### Peripheral neuropathy

Injury to the motor nerves in a peripheral nerve results in localized muscle atrophy and dysfunction of those myofibers innervated by those nerves. Damage to the suprascapular nerve results in unilateral scapular muscle (supraspinatus and infraspinatus) atrophy, and the clinical condition is known as sweency. In working draft horses, this nerve can be compressed by a poorly fitted harness collar. In nonharness horses, trauma is the most common cause. Traumatic injury to the radial nerve or axillary plexus is also relatively common in horses.

Sporadic pelvic limb neuropathy causing an exaggerated flexion of one or both limbs is known as stringhalt. It can be caused by trauma to the hind leg, ingestion of plant toxins, or can be of unknown cause. Outbreaks of stringhalt in pastured horses in Australia and New Zealand are the result of ingestion of *Hypochoeris radicata* and related species, also known as flatweed, false dandelion, and hairy cat's ear. Lesions of denervation atrophy are found in the distal lateral digital extensor muscle, and surgical removal of this muscle is one method of correction. Laryngeal hemiplegia due to denervation can also occur in affected horses (see later discussion). *Hypochoeris radicata* grows

## Pathologic Basis of Veterinary Disease, 4th Edition

---

prolifically in the Pacific Northwest and a similar syndrome of plant-induced stringhalt is said to occur there, but evidence to support this hypothesis has been hard to find, and feeding trials at Oregon State University have failed to reproduce the syndrome.

In addition to hamstring (semitendinosus, semimembranosus, and biceps femoris) muscle trauma, pelvic limb neuropathy as a result of trauma or unknown causes can cause the characteristic abnormal gait known as fibrotic myopathy, in which the forward swing of the affected pelvic limb is restricted. Affected muscle shows characteristic microscopic lesions of denervation atrophy.

Laryngeal hemiplegia is a well-documented condition in horses in which degenerative lesions within the left recurrent laryngeal nerve result in unilateral laryngeal muscle denervation atrophy (Fig. 15-22) and laryngeal dysfunction. Affected horses often make a characteristic respiratory noise during exercise, hence the name *roaring*. There are many possible causes of injury to the left recurrent laryngeal nerve, including extension of infections from the guttural pouches or tumors in that area, lead toxicity, and direct trauma. Most cases, however, are considered idiopathic. Although the exact cause of idiopathic laryngeal hemiplegia in horses is not known, the fact that it occurs only in tall, long-necked horses, and virtually never in ponies, suggests that whatever the mechanism of injury, very long nerves are predisposed.

Lead intoxication can also cause generalized peripheral neuropathy, muscle atrophy, and weakness mimicking equine motor neuron disease (see later discussion). Polyneuritis equi (neuritis of the cauda equina) and peripheral nerve lymphoma also cause denervation atrophy in horses. Polyneuritis equi most often involves the caudal nerve roots and facial nerves, and lymphoma has been found affecting multiple nerve roots or selectively involving the facial nerve.

15.2.2.1.5.2

### Motor neuronopathy

Damage to motor neurons in the brain stem or ventral horns of the spinal cord will result in degeneration of peripheral nerves. In the horse, protozoal myeloencephalitis due to *Sarcocystis neurona* is a common cause of unilateral denervation atrophy, usually of facial or gluteal musculature. Affected horses often also exhibit ataxia and proprioceptive deficits indicative of upper motor neuron and general proprioceptive pathway dysfunction (see Chapter 14).

Equine motor neuron disease occurs as the result of severe and prolonged vitamin E deficiency, which leads to motor neuron degeneration. Clinical signs are sudden onset of rapid muscle wasting, weakness, trembling, and increased time spent in recumbency. Type 1 motor neurons and muscles are preferentially affected, supporting the proposed pathogenesis of oxidative injury to motor neurons secondary to vitamin E deficiency. The severe denervation atrophy occurring in postural muscles (medial head of the triceps, vastus intermedius, sacrocaudalis dorsalis medialis) in horses with motor neuron disease often results in a remarkable pale yellow-tan color (Fig. 15-41, Fig. 15-11, C) and gelatinous texture of the affected muscle. Severely affected horses may become persistently recumbent, leading to death or euthanasia. In some cases, high-dose vitamin E supplementation (10,000 IU or more per day) can halt the progression of the disorder, and affected horses on vitamin E therapy can even develop some compensatory muscle hypertrophy and regain muscle mass. There is little or no evidence of reinnervation in this disorder, and affected horses are considered disabled for life.

1018

1019

Fig. 15-41 **Denervation atrophy, equine motor neuron disease, medial triceps muscle, horse.** The medial triceps muscle, a type 1 predominant postural muscle deep in the foreleg, is diffusely pale tan and gelatinous in appearance because of severe denervation atrophy. The adjacent muscles (*left and right*) have a normal appearance. (Courtesy College of Veterinary Medicine, Cornell University. For histopathologic findings, see [Fig. 15-23](#).)

Fig. 15-42 **Blackleg, hemorrhagic-necrotizing myositis (*Clostridium chauvoei*), thigh muscle, cow. A**, The dark red areas are caused by hemorrhagic necrosis of the underlying muscle. These lesions are characteristic of blackleg. **B**, *Clostridium chauvoei* can also produce substantial quantities of gas within infected tissues as shown here by the numerous (“pseudocystic”) spaces within hemorrhagic and necrotic muscle. **C**, Gram-positive bacilli are present in the serous exudate. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.2 MUSCULAR DISORDERS OF CATTLE

Although cattle have not been selected for muscle performance, many breeds have been selected for meat quality. This has led to selection for at least one genetic disorder. Disorders affecting muscle can have a profound economic effect on the cattle industry.

#### 15.2.2.2.1 Bacterial and Parasitic Myopathies

##### 15.2.2.2.1.1 Clostridial myositis (blackleg)

This disease, due to *Clostridium chauvoei*, is economically an extremely important disease that is most common in beef cattle. It can also occur in dairy cattle, especially those housed in free-stall barns. *Clostridium chauvoei* is a spore-forming, gram-positive anaerobic bacillus. Its spores are ubiquitous in the soil and following ingestion are capable of crossing the intestinal mucosa, entering the blood stream, and being carried to skeletal muscles. The spores lie dormant until localized trauma to the muscle, which in cattle is most often due to bruising during handling in a chute or from trauma in a crowded feedlot, results in muscle damage and localized hypoxia. The resultant anaerobic conditions allow the spores to activate and the bacteria to proliferate and produce toxins (Table 15-4) that cause capillary damage, hemorrhage, edema, and necrosis of adjacent myofibers.

The most common presentation is acute death. Signs before death are referable to toxemia; to the heat, swelling, crepitus, and dysfunction of the affected muscle group; and to fever. Serum concentrations of CK and AST are typically increased. Locally extensive hemorrhage and edema, often with crepitus due to gas bubbles, are seen in affected muscles and in overlying fascia and subcutaneous tissue. Necrotic muscle fibers appear dark red to red-black. Lesions are either wet and exudative (early lesions) or dry (later lesions) (Fig. 15-42, A). Cardiac muscle can also be involved. A characteristic odor of rancid butter due to butyric acid is typical. In other parts of the body, hemorrhages and edema can occur from the toxemia. Affected carcasses autolyze rapidly, likely due to the effects of clostridial toxins on tissue and of high body temperature before death. Histologically, locally extensive areas of muscle fibers undergoing coagulation necrosis and fragmentation, and interstitial edema and hemorrhage are seen. Overt vasculitis is not seen. Gas bubbles are typical. Gram-positive bacilli whose appearance is compatible with that of *Clostridium chauvoei* may be demonstrable within affected muscle (Fig. 15-42, C).

1019

1020

Isolation of *Clostridium chauvoei* on anaerobic media or visualization by fluorescent antibody techniques are useful for the diagnosis of blackleg, but are confirmatory only if typical gross and histopathologic lesions are present, as dormant spores of *Clostridium chauvoei* can be found in normal muscle. The vaccination history and evaluation of husbandry practices are also important; unvaccinated or poorly vaccinated animals in situations in which muscle trauma is possible are most at risk. There is generally no effective treatment for cattle with blackleg, and death occurs rapidly. Prevention is the best treatment. Vaccination against clostridial toxins and maintenance of a safe environment are critical.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

15.2.2.2.1.2

### Botulism

Botulism due to ingestion of *Clostridium botulinum* toxin from contaminated feed or soil occurs in cattle, and clinical signs and pathogenesis are similar to those in the adult horse. Cattle are most susceptible to type C and D botulinum toxins, and herd outbreaks are possible. Cattle, however, are much more resistant to botulism than are horses. Botulinum toxin within silage, haylage, or hay is the most common cause of outbreaks of botulism in cattle. Abnormal eating habits (pica) can result in ingestion of *Clostridium botulinum* toxin from the soil or carrion. Botulism in cattle is usually fatal.

15.2.2.2.1.3

### Pyogenic bacteria

Cattle are prone to develop abscesses caused by pyogenic bacteria, most commonly *Arcanobacterium pyogenes*. Abscesses in muscle occur most commonly in the hind leg. Swelling and lameness of the affected limb because of widespread necrotizing cellulitis and myositis are seen.

*Arcanobacterium pyogenes* is a ubiquitous bacterium that can infect muscle by two routes: by direct contamination of wounds and injection sites and hematogenously. The bacterium can be found within the reproductive tract of cows and within the rumen wall, and it has been speculated that *Arcanobacterium pyogenes* from a transient bacteremia after parturition or from disruption of the rumen wall can result in colonization of damaged muscle. Lesions vary depending on the virulence of the bacteria and the age of the lesions. They vary in extent from encapsulated intramuscular abscesses adjacent to the site of injection to a diffuse purulent cellulitis extending down the tissue and fascial planes. The cellulitis may be so severe as to involve much of the musculature of the affected limb. Grossly, encapsulated abscesses are filled with thick, yellow-green, foul-smelling pus. In cases of cellulitis, pus dissects along fascial planes outside the muscle and between perimysial sheaths within muscles. Inflammation extends into the adjacent myofibers, resulting in myonecrosis and subsequent replacement by fibrous tissue. The greenish color of the exudate is distinctive, and small gram-positive pleomorphic bacteria are often seen within tissue sections or cytologic preparations. *Arcanobacterium pyogenes* is readily isolated on aerobic culture.

15.2.2.2.1.4

### *Actinobacillus lignieresii* (wooden tongue)

Infection of oral tissue, particularly of the tongue musculature, by *Actinobacillus lignieresii* results in a severe chronic suppurative and fibrosing myositis. Infection occurs through oral wounds or by penetrating plant fragments. Affected cattle have difficulty prehending and swallowing, and often have excessive salivation. Histologic features are of marked fibrosis with microabscesses containing eosinophilic material ("radiating clubs") and characteristic gram-negative bacilli. Aggressive antibiotic therapy can be curative.

15.2.2.2.1.5

### *Actinomyces bovis* (lumpy jaw)

*Actinomyces bovis* frequently involves bones of the jaw, causing chronic suppurative and fibrosing osteomyelitis. Occasionally *Actinomyces bovis* involves the musculature of the tongue, causing gross and histologic lesions similar to those caused by *Actinobacillus lignieresii*. Gram stain reveals gram-positive bacilli, which distinguishes this lesion from the gram-negative *Actinobacillus lignieresii* infection.

### Protozoal myopathies

Intracytoplasmic protozoal cysts of *Sarcocystis* spp. are common incidental findings in skeletal and cardiac myofibers of cattle (Fig. 15-31). Massive exposure may result in fever, anorexia, and progressive wasting, but this is uncommon. More often, *Sarcocystis* infection is diagnosed as an incidental finding at necropsy or during meat inspection at slaughter. If the cyst wall breaks down, a focus of myofiber necrosis and later granuloma formation results.

Eosinophilic myositis is a disease of cattle thought to be a relatively uncommon manifestation of *Sarcocystis* infection that may involve hypersensitivity. There is overt green discoloration (Fig. 15-12) of affected muscles caused by the massive infiltration of eosinophils (Fig. 15-43, A and B). This is accompanied by myofiber necrosis and, in chronic cases, fibrosis. Fragments of degenerating intralesional protozoa can sometimes be found (Fig. 15-43, C).

Cattle can also be infected with *Neospora caninum*. Adults have no clinical disease, but infection of the fetus can cause nonsuppurative inflammation of skeletal muscle and of heart and brain.

1020

Bildfell, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 15.2.2.2.2 Nutritional and Toxic Myopathies

#### 15.2.2.2.2.1 Nutritional myopathy

Similar to horses, calves and young cattle are susceptible to nutritional myopathy because of selenium or (less commonly) vitamin E deficiency. But the profound involvement of temporal and masseter muscles (“maxillary myositis”) that can occur in horses is not seen in cattle. In the latter species, the postural muscles and muscles of locomotion are most commonly affected. Muscles of affected calves appear pale pink to white, often in a patchy distribution. The gross appearance depends on the extent of the necrosis and the stage of the lesion. In early stages, yellow and white streaks are present, and later pale, chalk white streaks often appear, thus the common name *white muscle disease* (Fig. 15-44).

**Fig. 15-44 Nutritional myopathy (white muscle disease), skeletal muscles of the caudal thigh, sagittal section, calf.** In this early stage, affected muscles have yellow and white streaks, often in a patchy distribution. These streaks are areas of necrotic myofibers. Later as the necrotic myofibers calcify, white streaks (chalky texture, mineralization) are visible grossly. (Courtesy Dr. G. K. Saunders, Virginia-Maryland College of Veterinary Medicine; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

15.2.2.2.2

### Plant toxicities

*Cassia occidentalis* (coffee senna, coffee weed) is the most common cause of degenerative myopathy in cattle due to plant toxicity in cattle. This plant grows throughout the southeastern United States. Pale areas within skeletal muscle, with lesser involvement of cardiac muscle, are due to fiber necrosis, generally with minimal to no mineralization. Other plant toxicities are discussed in the toxic myopathies section.

15.2.2.2.3

### Ionophore toxicity

The pathogenesis of ionophore toxicity is discussed in the toxic myopathy section. Ionophore toxicity in cattle is seen only with overdoses because of improper feed mixing. Anorexia, diarrhea, and weakness are the primary clinical signs. Serum concentrations of CK and AST are often extremely high. Pale areas within skeletal and cardiac muscle are due to myofiber necrosis. In animals that survive, regeneration will restore the skeletal muscle integrity, but cardiac lesions heal by fibrosis.

1021

1022

15.2.2.3

### Congenital or Inherited Disorders

15.2.2.3.1

#### Steatosis

This disease in cattle, sometimes called lipomatosis, is most often recognized as an incidental finding at necropsy or at slaughter. This disorder is thought to be the result of defective muscle development, in which large areas of myofibers are replaced by adipocytes. An inherited basis has not been established. Lesions can be symmetric or asymmetric, with the most severely affected muscles being those of the back and loin (longissimus muscles; [Fig. 15-11, D](#)). Severely affected muscles are composed entirely of fat, whereas less severely affected muscles appear streaked because of partial replacement by fat. Histologically the space normally occupied by myofibers is filled with mature adipocytes. In utero denervation or failure of innervation will result in a similar muscle lesion ([Fig. 15-29](#)), and careful evaluation of the peripheral nerves and spinal cord is indicated.

Diagnosis is readily made on gross examination and can be confirmed by histologic examination, specifically in sections stained with oil-red-O or Sudan black for fat. As this condition is usually not diagnosed during life and the loss of myofibers is irreversible, treatment is neither necessary nor possible.

15.2.2.3.2

#### Other bovine congenital or inherited myopathies and neuronopathies

Congenital muscular hyperplasia (“double muscling”) due to defects in the myostatin gene occurs in a variety of cattle breeds. An unusual multisystemic disease with characteristic necrotizing vasculopathy occurs in young Gelbvieh cattle. Glycogenosis type II (acid maltase deficiency) has been recognized in shorthorn and Brahman cattle, and glycogenosis type V (myophosphorylase deficiency) occurs in Charolais cattle. An inherited motor neuron degenerative disease occurs in Brown Swiss cattle. These disorders are discussed in more detail in [Appendix 15-1](#).

### 15.2.2.2.4 Electrolyte Abnormalities

#### 15.2.2.2.4.1 Hypokalemic myopathy

Decreased potassium interferes with normal muscle cell function and can lead to muscle weakness and myofiber necrosis. Type 2 fibers are preferentially affected. The pathogenesis of hypokalemic myopathy is not clear, but myofiber necrosis may be the end result of either decreased myofiber energy production or of focal ischemia secondary to vasoconstriction. Hypokalemia can also interfere with normal cardiac conduction, and atrial fibrillation is common. Hypokalemia in cattle can be due to anorexia. A history of ketosis occurring within a month of parturition is common. Glucocorticoids with high mineralocorticoid activities, such as isoflupredone acetate used to treat ketosis, are a recognized cause of hypokalemic myopathy in cattle. Activation of glucose transport into cells by intravenously administered glucose or insulin will also cause intracellular movement of potassium and can result in hypokalemia. No specific findings are present at postmortem examination, although ischemic necrosis secondary to recumbency can be seen in muscles of the hindlimbs (see later discussion). Examination of muscles not involved in weight-bearing reveals multifocal polyphasic myofiber necrosis and vacuolated myofibers (vacuolar degeneration), indicative of myodegeneration as a direct effect of hypokalemia.

Affected cows are profoundly weak and become recumbent and unable to support the weight of their heads. Serum concentration of potassium is below normal ( $<2.3$  mEq/L), and CK and AST levels are moderately high. The diagnosis is based on typical historical and clinical findings and a low serum potassium concentration. Intravenous and oral supplementation with potassium salts and supportive therapy may result in recovery in some cases, but this disorder is often fatal.

#### 15.2.2.2.4.2 Other electrolyte abnormalities

Both hypocalcemia and hypophosphatemia can result in profound muscle weakness and recumbency in cattle. In hypocalcemia, weakness is primarily due to disruption of neuromuscular transmission. Significant changes are not seen in affected muscles, although ischemic necrosis can occur secondary to recumbency (see later discussion). Diagnosis relies on clinical findings and identification of abnormal serum electrolyte concentrations. Treatment includes correction of the electrolyte defect by intravenous administration of the appropriate electrolyte-containing fluids, supportive care, and correction of any dietary abnormalities that may predispose to electrolyte problems.

#### 15.2.2.2.5 Ischemic Myopathy

Ischemic muscle necrosis due to recumbency is common in cattle. The muscular lesion is similar to that seen in other species, but in cattle prolonged sternal recumbency is more common than lateral recumbency, and pectoral muscles and muscles of limbs tucked under the body or splayed out limbs will be most prone to injury ([Fig. 15-30](#)).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.3 MUSCULAR DISORDERS OF SMALL RUMINANTS

Selection pressures and economic consequences of muscle disorders similar to those in beef cattle exist in small ruminants raised for meat. In goats, selection for an interesting mutant has resulted in perpetuation of myotonia.

1022

#### 15.2.2.3.1 Bacterial and Parasitic Myopathies

1023

##### 15.2.2.3.1.1 Clostridial myositis (blackleg)

This disorder occurs occasionally in sheep and goats and is similar to the disease in cattle.

##### 15.2.2.3.1.2 Botulism

Botulism can occur in small ruminants, but, as in cattle, it is rare.

##### 15.2.2.3.1.3 Protozoal myopathy

Intracytoplasmic cysts of *Sarcocystis* spp. are commonly found within skeletal and cardiac muscle fibers of sheep and goats as an incidental finding, similar to cattle. Eosinophilic myositis due to sarcocystosis is rare in sheep and is not recognized in goats. In camelids, massive infection with *Sarcocystis* can occur (Fig. 15-45), especially in animals imported from South America where sarcocystosis is common. In rare cases, *Sarcocystis* infection in camelids is associated with widespread eosinophilic myositis.

#### 15.2.2.3.2 Nutritional and Toxic Myopathies

Degenerative myopathy due to nutritional deficiency or toxin ingestion is relatively common in many small ruminant species. The eating habits of goats make them particularly likely to ingest poisonous plants.

##### 15.2.2.3.2.1 Nutritional myopathy

Young goats and sheep are susceptible to degenerative myopathy associated with selenium or, less commonly, vitamin E deficiency. A similar disorder occurs rarely in young camelids. The disease in these species is similar to the disease in young cattle.

##### 15.2.2.3.2.2 Toxic myopathies

Sheep and goats are susceptible to plant and ionophore toxicities similar to those in cattle. In goats, ingestion of honey mesquite (*Prosopis glandulosa*) causes degeneration of the motor nucleus of the trigeminal nerve, resulting in denervation atrophy of the muscles of mastication, and consequent inability to adequately chew feed, leading to progressive emaciation.

Fig. 15-45 **Sarcocystosis, skeletal muscle, alpaca.** Multiple pale nodules within the muscle indicate the location of *Sarcocystis* cysts. (Courtesy College of Veterinary Medicine, Cornell University.)

### 15.2.2.3.3 Congenital or Inherited Myopathies

#### 15.2.2.3.3.1 Myotonia in goats

Myotonia in the goat is inherited as an autosomal dominant trait, and the variable clinical severity is attributable to increased severity in homozygotes compared with heterozygotes. The genetic defect affects the skeletal muscle chloride channel, resulting in decreased chloride conductance and associated ionic instability of the sarcolemma. Affected goats develop severe muscle spasms in response to sudden voluntary effort, for example when startled by the blowing of a locomotive horn, starting at about 2 weeks of age. Episodes of myotonia can last from 5 to 20 seconds and are characterized by generalized stiffness and adoption of a “sawhorse” stance. Goats often fall over. Sustained muscle dimpling occurs after percussion. Serum concentrations of CK and AST are normal. Concentric needle electromyography reveals the characteristic waxing and waning (“dive bomber”) spontaneous activity of myotonia. There are no gross pathologic findings. Histologically, muscle fibers in affected goats may show moderate hypertrophy. But characteristic abnormalities are revealed only with ultrastructural examination in which dilated and proliferated T tubules and terminal cisternae of sarcoplasmic reticulum are seen. Diagnosis is based on characteristic clinical signs and EMG findings. There is no treatment for this disorder, and it is rarely fatal. Affected animals are actually prized by collectors of so-called fainting goats. If nothing else, housing for these animals is simplified, as fencing need not be nearly as high as that required for normal goats.

#### 15.2.2.3.3.2 Other inherited myopathies

An inherited myopathy (ovine muscular dystrophy) in Merino sheep and an inherited glycogen storage myopathy have been identified in sheep in Australia. These disorders are discussed in more detail in [Appendix 15-1](#).

### 15.2.2.3.4 Megaesophagus in Camelids

The esophagus of camelids contains a large amount of skeletal muscle, and adult llamas and alpacas are prone to develop abnormal motility and dilation of the esophagus (megaesophagus). Affected animals often lose body condition and exhibit abnormal rumination of feed boluses. Histopathologic findings of angular atrophy of type 1 and type 2 fibers suggest that this disorder is an acquired denervating disease, but further studies are necessary.

### 15.2.2.4 MUSCULAR DISORDERS OF PIGS

The economic impact of muscle disease in pigs is profound. The high percentage of pigs with the genetic defect that predisposes to malignant hyperthermia is another example of selection pressure leading to skeletal muscle genetic mutations.

1023

### 15.2.2.4.1 Bacterial and Parasitic Myopathies

1024

#### 15.2.2.4.1.1 Clostridial myositis (malignant edema)

Pigs occasionally develop clostridial myositis (*Clostridium* spp.) particularly at sites of intramuscular injection. The resulting disease is similar to that seen in cattle, sheep, and goats, although heart involvement appears to be rare.

#### 15.2.2.4.1.2 Pyogenic bacteria

Abscesses within muscles and their fascia as a result of infection by pyogenic bacteria, such as *Arcanobacterium pyogenes*, are common in pigs and are similar to those in cattle.

#### 15.2.2.4.1.3 Trichinosis

Infection of pigs by the nematode parasite *Trichinella spiralis* is of major economic importance to the porcine industry and poses a serious health hazard to human beings. Pigs infected with *Trichinella spiralis* show no clinical signs.

The adult nematode resides in the mucosa of the small intestine. Larvae penetrate the intestinal mucosa and enter the blood stream, through which they gain access to the muscle. Larvae invade and encyst within myocytes. Encysted larvae are typically not visible on gross examination, although dead larvae can calcify and be visible as 0.5- to 1-mm white nodules (Fig. 15-46, A). Active muscles such as the tongue, masseter, diaphragm, and intercostal, laryngeal, and extraocular muscles are preferentially affected. Focal inflammation consisting of eosinophils, neutrophils, and lymphocytes occurs associated with invasion of the muscle by *Trichinella* larvae. After cyst formation, the larvae are protected from the host's immune response, and inflammation is minimal to absent (Fig. 15-46, B).

Diagnosis is based on identification of the characteristic nematode larvae encysted within muscle fibers. In those cases in which the larvae have died and calcified, a presumptive diagnosis of trichinosis can still be made.

## Pathologic Basis of Veterinary Disease, 4th Edition

15.2.2.4.1.4

### Protozoal myopathies

Intracytoplasmic cysts of *Sarcocystis* spp. are not common in pigs but can occasionally be found in the skeletal and cardiac muscle fibers as an incidental finding. Eosinophilic myocarditis has been reported following experimental infection.

15.2.2.4.2

### Nutritional and Toxic Myopathies

15.2.2.4.2.1

### Nutritional myopathy

Young pigs are susceptible to degenerative myopathy because of selenium or vitamin E deficiency, and the pathologic changes are similar to those seen in calves. A distinctive clinical disorder seen in very young Vietnamese pot-bellied pigs, in which affected piglets have a short, stilted gait and tend to stand on their toes, is thought to be related to selenium or vitamin E deficiency. Histologically, there is a multifocal polyphasic degenerative myopathy. Affected piglets appear to recover spontaneously.

**Fig. 15-46 Trichinosis, encysted larvae, diaphragm, bear.** **A**, Encysted larvae of *Trichinella spiralis* appear as pale elongated foci in the muscle. **B**, Encysted larvae of *Trichinella spiralis* incite minimal inflammation until they die. Formalin fixation, H&E stain. (**A and B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

15.2.2.4.2.2

### Toxic myopathies

Pigs are susceptible to poisoning by *Cassia occidentalis* and develop segmental necrosis of myofibers, especially in the diaphragm. Monensin toxicity results in segmental necrosis of skeletal muscle and necrosis of cardiac muscle, particularly atria. The pathogenesis of ionophore toxicity is discussed in the section on Toxic Myopathies. Gossypol present in cottonseed products is toxic to pigs when these products are fed at 10% or more of the ration and causes skeletal and cardiac muscle necrosis as well as lesions in the liver and lung.

1024

15.2.2.4.3

### Congenital and Inherited Myopathies

1025

15.2.2.4.3.1

#### Myofibrillar hypoplasia (splayleg)

This congenital disorder affects young piglets and results in splaying of the limbs to the side (abduction). Affected animals propel themselves by pushing against the ground with the pelvic limbs. This posture results in progressive flattening of the sternum. Although delayed myofibril development has been suggested, the histopathologic findings are inconclusive because similarly poorly developed myofibers can be seen in normal littermates. Affected piglets can recover with treatment, which includes the use of a harness that partially supports their bodies, holds their legs under their bodies, and encourages locomotion. Providing affected pigs with a nonslip floor is also important.

15.2.2.4.3.2

#### Steatosis

Pigs can have large areas of muscle replaced by mature adipose tissue, similar to that described in cattle.

15.2.2.4.3.3

#### Malignant hyperthermia (porcine stress syndrome; pale soft exudative pork)

This disorder affects several strains of pigs, most commonly those with unpigmented hair coats. A similar syndrome occurs in Vietnamese pot-bellied pigs. Incidence varies, but can be very high within certain herds. The disease in pigs is an accurate animal model of the disease in human beings and is an important cause of economic losses in the pig industry. Susceptibility to malignant hyperthermia is inherited as an autosomal recessive trait. The genetic defect results in abnormal activity of the skeletal muscle ryanodine receptor. The ryanodine receptor is a calcium release channel located in the sarcoplasmic reticulum terminal cisternal membrane that links the T tubule to the sarcoplasmic reticulum during excitation-contraction coupling. Uncontrolled intracytoplasmic calcium release because of abnormal ryanodine receptor activity leads to excessive contraction and heat production. Clinical disease occurs only in pigs homozygous for the defect, although human heterozygotes can also be susceptible to hyperthermic episodes following halothane anesthesia. It is suspected that this defect originated years ago in a foundation animal and resulted in offspring with increased muscling and reduced body fat. Affected pigs are clinically normal until an episode of hyperthermia is triggered by a precipitating factor, such as halothane anesthesia or stress. Episodes consist of severe muscle rigidity and dramatically increased body temperature. Severe cases progress rapidly to death. Serum concentrations of CK and AST are markedly increased during episodes.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In animals dying during a hyperthermic episode, affected muscles are pale, moist, and swollen and appear “cooked” (Fig. 15-47), hence the common name “pale, soft, exudative pork.” Muscles of the shoulder, back, and thigh are preferentially affected. Affected fibers are either hypercontracted or, if the animal has survived for some hours, undergoing coagulation necrosis. Histopathologic findings in susceptible pigs sampled during clinically normal periods include chronic myopathic change (fiber-size variation, internal nuclei) and rare necrotic fibers.

**Fig. 15-47 Malignant hyperthermia, (porcine stress syndrome; pale soft exudative pork), lumbar epispinal muscles, transverse section, pig.** The affected muscles are pale pink, moist, and swollen and have a “cooked” pork appearance (“parboiled”). (Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

This disorder is most commonly diagnosed in pigs dying acutely and is made based on the clinical history of a precipitating stress and on the characteristic gross and histopathologic findings. Given that the precise defect is known, genetic testing allows for identification of carrier and affected animals. Avoidance of precipitating stress factors in susceptible pigs and removal of carrier and affected animals from the breeding stock will reduce the incidence of this disorder.

### 15.2.2.4.4

#### Ischemic Myopathy

Large pigs are susceptible to ischemic myopathy secondary to recumbency, resulting in ischemic necrosis similar to that seen in horses and cattle. The proximal limb muscles are most susceptible.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.5 MUSCULAR DISORDERS OF THE DOG

Selection pressures for a certain type of muscular development are far less frequent in dogs than in livestock. A few disorders, such as myotonia, have been suggested to occur more often in dogs originally bred for meat, but this is pure speculation. The canine genome may have genes prone to new mutations, similar to human beings, leading to genetic disorders, such as X-linked muscular dystrophy. In general, the impact of muscular disorders in dogs is much less than in livestock. Dogs with muscular weakness can still make good house pets.

1025

1026

#### 15.2.2.5.1 Parasitic Myopathies

##### 15.2.2.5.1.1 Protozoal myopathy

The parasitic diseases affecting skeletal muscle in the dog are primarily caused by protozoal organisms, of which *Neospora caninum* is the most important. It is now suspected that early reports of myositis and radiculoneuritis caused by *Toxoplasma gondii* in young dogs were actually *Neospora caninum* infections. *Neospora caninum* is often transmitted in utero, and evidence suggests that affected bitches are chronic carriers of the organism. Both the peripheral nervous system and the skeletal muscle are invaded by organisms. Ventral spinal roots are preferentially involved, and damage results in denervation atrophy of muscles. Signs of progressive neuromuscular weakness, most profound in the pelvic limbs, begin in affected pups several weeks of age. Marked muscle atrophy of the pelvic limb muscles occurs rapidly, and fixation of pelvic limb joints occurs as a result of denervation of muscle in an actively growing limb. Serum concentrations of CK and AST may be slightly increased. Concentric needle electromyography reveals dense, sustained spontaneous activity (fibrillations and positive sharp waves) consistent with denervation.

Pelvic limb muscles are severely atrophied, firm, and pale. Fixation of the pelvic limb joints persists after anesthesia or death. Scattered foci of mixed inflammation with associated segmental myofiber necrosis are often seen within skeletal muscle, and characteristic intracytoplasmic protozoal cysts may be present.

*Neospora caninum* infection should be suspected based on characteristic progressive neuromuscular dysfunction in a young growing pup. Infection of older dogs is also possible but is uncommon. The finding of a mixed inflammatory-neuropathic lesion within affected skeletal muscle should prompt a search for protozoa, although these are often present in small numbers and may not be seen. Serologic tests can detect antibodies to *Neospora caninum*, and antibodies are available for immunohistochemical studies of paraffin-embedded, formalin-fixed tissue. Antiprotozoal treatment may kill the organisms, but denervation atrophy and pelvic limb fixation will persist.

*Hepatozoon americanum* and *Trypanosoma cruzi* are other protozoal organisms that can affect canine skeletal muscle. These parasitic diseases are discussed in more detail in [Appendix 15-1](#).

##### 15.2.2.5.1.2 Other parasites

Rarely, cysts of *Trichinella spiralis* are found as an incidental finding in canine muscle.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.5.2 Congenital or Inherited Myopathies

#### 15.2.2.5.2.1 X-linked muscular dystrophy (Duchenne's type)

This disorder has been confirmed or suspected in several breeds of dogs, including Irish terrier, golden retriever, Labrador retriever, miniature schnauzer, rottweiler, Dalmatian, Shetland sheepdog, Samoyed, Pembroke Welsh corgi, Japanese spitz, and Alaskan malamute. This canine disorder is homologous to Duchenne's muscular dystrophy of human beings and involves defects in the dystrophin gene, which codes for a membrane-associated cytoskeletal protein present in skeletal and cardiac muscle. The absence of dystrophin renders skeletal muscle fibers susceptible to repeated bouts of necrosis and regeneration. Necrosis of cardiac myocytes also occurs and is followed by replacement with connective tissue, resulting in a progressive cardiomyopathy. This disorder is inherited as an X-linked recessive trait, affecting approximately 50% of males born to a female carrier. Experimentally, affected females have been produced from breeding of an affected male to a carrier female. It is suspected that new mutations in the canine dystrophin gene may be relatively common, as is the case in human beings. Therefore this disorder could occur in any breed, including crossbreeds. There is variable severity of clinical disease even within littermates, and small breed dogs are often less severely affected than are large breed dogs.

Severely affected pups develop a rapidly progressive weakness and die within the first few days of life. In less severely affected dogs, clinical signs are a stiff, short-strided gait and exercise intolerance beginning at 8 to 12 weeks of age, followed by progressive weakness and muscle atrophy. Development of a degree of joint contracture and splaying of the distal limbs is typical (Fig. 15-48). Weakness of the tongue, jaw, and pharyngeal muscles results in difficulty with prehension and swallowing of food, and affected dogs often drool excessively. Involvement of skeletal muscle within the esophagus can result in megaesophagus, regurgitation, and aspiration pneumonia. Markedly increased concentrations of serum CK, AST, and alanine aminotransferase (ALT) are characteristic, even before the onset of obvious clinical disease. Concentric needle electromyography reveals remarkable spontaneous activity in the form of pseudomyotonic bursts. Muscles do not dimple with percussion.

In pups dying within the first few days of life, the thin superficial muscles of the shoulder, neck, and pelvic limbs (trapezius, brachiocephalicus, deltoid, and sartorius), and the diaphragm have pale yellow –to–white streaks throughout (Fig. 15-11, A). Death in these cases is thought to be caused by respiratory failure related to severe diaphragmatic myonecrosis. In animals with clinical disease beginning at 8 to 12 weeks, pale streaks within muscle are much less evident, although affected muscles often appear diffusely pale and may be fibrotic. All skeletal muscles, with the exception of the extraocular muscles, appear to be affected to varying degrees. Overt myofiber necrosis is most severe in earlier stages of the disorder and typically affects small clusters of contiguous fibers. Scattered large, darkly stained fibers (“large dark fibers”) in the early stages of hypercontraction and necrosis are common (Fig. 15-16, A). Regeneration of affected segments occurs rapidly, and characteristically both myofiber necrosis and fiber regeneration are present within the same section (i.e., the lesion is a multifocal polyphasic necrosis) (Fig. 15-49). Scattered mineralized fibers can also be found. With time, ongoing necrosis and regeneration are less common, and endomysial fibrosis occurs. Chronically affected muscles can have remarkable fibrosis, infiltration by adipocytes, and other chronic myopathic changes. Fiber-type conversion can also be seen as a chronic myopathic change.

1026

1027

Fig. 15-48 **Canine muscular dystrophy, X-linked muscular dystrophy, adult golden retriever.** Note the diffuse muscle wasting and splaying (outward rotation) of the forelimbs. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

In all dogs 6 months of age or older, multifocal pale yellow-to-white zones will be present within the heart, predominantly involving the subepicardial region of the left ventricular wall, the papillary muscles, and the ventricular septum. Histologically, necrosis, mineralization, and progressive dissecting myocardial fibrosis are found. Death in older animals is due either to aspiration pneumonia secondary to dysphagia or to progressive cardiac failure, although affected dogs may survive for many years.

**Fig. 15-49 Canine muscular dystrophy, X-linked muscular dystrophy, biceps femoris muscle, transverse section, dog.** The numerous large dark fibers (*left*) are undergoing acute necrosis, and the cluster of small-diameter fibers with large prominent nuclei (*top right*) are regenerating. The presence of both necrotic and regenerating fibers is indicative of polyphasic necrosis. Frozen section, modified Gomori's trichrome stain. (Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.)

The diagnosis should be suspected based on characteristic clinical findings in a young male dog but must be confirmed by muscle biopsy and analysis of muscle for dystrophin. The absence of dystrophin in muscle fibers of affected dogs can be confirmed using immunohistochemical staining on frozen sections (Fig. 15-50) or by Western blot analysis. There is no treatment for this disorder.

Carrier females show no clinical signs, but scattered necrotic and regenerating fibers and moderate increases in serum CK and AST are common in young carriers. At birth, dystrophin in carriers is expressed in a mosaic pattern in both cardiac and skeletal muscle (Fig. 15-50, C). Because they are multinucleate, skeletal myofibers are able to eventually up-regulate and translocate dystrophin to restore this protein within the entire myofiber. Fiber necrosis is therefore rare in older carriers. Cardiac muscle, however, remains mosaic for life. Foci of necrosis and development of fibrosis occurs in the cardiac muscle of carrier females, but to-date none have developed overt cardiac failure. Any female dog producing affected pups is a carrier, and approximately half of all of her female offspring will also be carriers. Carrier females can also be identified either by dystrophin or DNA analysis and should be spayed.

### 15.2.2.5.2.2

#### Other canine muscular dystrophies

Dystrophin has been found to be associated with a series of dystrophin-associated proteins, forming a membrane complex. The genes for many of these proteins are autosomally inherited; therefore not all

1027

1028

## Pathologic Basis of Veterinary Disease, 4th Edition

---

canine muscular dystrophies are X-linked disorders. Autosomal recessive inheritance of dystrophin-associated gene defects leading to muscular dystrophy is common in human beings, and defects in dystrophin complex proteins leading to non-Duchenne's type muscular dystrophy have also been identified in various breeds of dogs. These are discussed in more detail in [Appendix 15-1](#).

**Fig. 15-50 Dystrophin localization in transverse sections of canine muscle, immunostain for dystrophin, skeletal muscle. A,** Normal dog. Note that the dystrophin is localized at the sarcolemma. Frozen section, immunoperoxidase reaction for dystrophin. **B,** X-linked muscular dystrophy, dog. Dystrophin is completely absent. Frozen section, immunoperoxidase reaction for dystrophin. **C,** X-linked muscular dystrophy carrier, young carrier female dog. Note the mosaic pattern in which some fibers contain normal dystrophin and others completely lack dystrophin. Frozen section, immunoperoxidase reaction for dystrophin. (**A, B, and C,** Courtesy Dr. B.J. Cooper, College of Veterinary Medicine, Oregon State University.)

### Labrador retriever myopathy

This disorder is inherited as an autosomal recessive trait. Affected dogs occur within the working or sporting breed lines rather than the show dog lines. Despite extensive study, the underlying defect is not known. Recent studies suggest similarity to inherited centronuclear myopathy of human beings. Affected Labrador retrievers develop signs of neuromuscular weakness within the first 6 months of life. Exercise intolerance leads to collapse during prolonged exercise, and episodes of collapse can also be elicited by exposure to cold. Loss of triceps and patellar reflexes is characteristic. Affected dogs usually do not develop normal musculature. Concentric needle electromyography reveals intense and abnormal spontaneous activity with normal motor nerve conduction velocities. Serum concentrations of CK and AST are often normal, although they can be mildly to moderately increased. Megaesophagus can be present.

The only specific abnormalities seen at necropsy are poor muscling and possibly megaesophagus. On histologic examination, affected dogs have remarkable myopathic changes characterized by clusters of atrophic myofibers, myofiber hypertrophy, and internal nuclei (Fig. 15-51). Abnormal mitochondrial distribution, often with peripheral mitochondrial aggregates (identified as ragged red fibers in frozen sections stained with Gomori's modified trichrome stain), can also be seen (Fig. 15-28, B). A primary defect of the myofiber is suspected, but segmental necrosis and regeneration are rare. Therefore this disorder does not qualify as a muscular dystrophy. Although the initial reports described this disorder as a type 2 deficiency myopathy, further studies have shown that fiber-type proportions vary remarkably between muscles and between dogs, although an increase in type 1 fibers (type 1 fiber predominance) is often seen. Alteration of the normal mosaic pattern of myofiber types is also seen. There is fiber-type grouping, usually considered a neuropathic change, despite the absence of peripheral nerve lesions. These changes are thought to reflect fiber-type conversion unassociated with denervation.

Based on the clinical findings, the diagnosis may be suspected but should be confirmed by a muscle biopsy. There is no treatment for the disorder, although the disease is nonprogressive after 6 months to 1 year of age, and affected animals can still be kept as pets. Dogs producing affected pups should not be rebred.

1028

1029

**Fig. 15-51 Labrador myopathy, skeletal muscle, transverse section, Labrador dog.** There is excessive fiber-size variation, and some fibers contain one or rarely two internal nuclei. Nuclei are abnormally large. Frozen section, H&E stain. (*Courtesy Dr. B.A. Valentine, College of Veterinary Medicine, Oregon State University.*)

15.2.2.5.2.4

### Congenital myotonia

Myotonia is seen most commonly in the Chow chow dog, miniature schnauzer, and Staffordshire terrier. Autosomal recessive inheritance has been confirmed in the miniature schnauzer, and available evidence supports similar inheritance in the Chow chow. The underlying cellular defect in miniature schnauzers is decreased chloride conduction, and a similar defect is suspected in Chow chow dogs. Affected pups can begin to show signs of a stiff gait as early as 6 weeks of age. The signs progress for several months, and then stabilize with variable severity. Affected dogs move with splayed, stiff thoracic limbs and often “bunny hop” in the pelvic limbs. Signs are most severe on initiation of movement and improve with continued exercise. But affected dogs are never clinically normal. During severe episodes, dogs can fall over, and laryngospasm can result in transient dyspnea and even cyanosis. The musculature becomes remarkably hypertrophied, and sustained muscle dimpling occurs after percussion. Characteristic waxing and waning (“dive bomber”) myotonic bursts are found with concentric needle EMG. Serum concentrations of CK and AST are normal or mildly increased.

Overall muscle hypertrophy, with prominently defined muscle groups, is the only finding on postmortem examination. In early stages of the disease, muscle appears relatively normal on histologic examination. With time, myofiber hypertrophy and myofiber atrophy of both type 1 and type 2 fibers, and rare scattered segmental necrosis or regeneration, are seen. Fibrosis is mild to inapparent.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Diagnosis is based on clinical signs and can be confirmed by concentric needle electromyography or by examination of a muscle biopsy. Molecular testing is available to detect carrier and affected miniature schnauzers. Therapeutic agents that act to stabilize excitable cell membranes, such as quinidine, procainamide, and phenytoin, can relieve some of the signs of myotonia.

15.2.2.5.2.5

### Swimmer pups

These puppies are clinically similar to piglets with splayleg. Affected pups cannot adduct the limbs beneath their bodies, and develop a characteristic “swimming” gait, and progressive flattening of the sternum. Although this syndrome can occur in pups with neuromuscular disease of any sort that leads to weakness, it is more commonly associated with overfeeding leading to excess body weight. Affected overfed pups often recover after reduction in total daily milk intake, provision of a nonslippery floor surface, and development of harnesses and physical therapy to encourage them to bring their legs underneath their bodies and walk. Sternal flattening and abnormal lateral deviation of the limbs are consistent findings. Histopathologic abnormalities in muscle will vary depending on the cause and will be absent in pups in which this disorder simply reflects overfeeding.

15.2.2.5.3

### Endocrine Myopathies

15.2.2.5.3.1

#### Hypothyroidism

Because of its role in muscle metabolism, decreased thyroid hormone often results in skeletal myofiber weakness and atrophy. Hypothyroidism can also cause a peripheral neuropathy, and damage to motor nerves can cause denervation atrophy and contribute to the neuromuscular weakness. Signs of neuromuscular dysfunction due to hypothyroidism are extremely varied and include generalized weakness, muscle atrophy, laryngeal paralysis, and megaesophagus. Electromyographic studies are often normal; abnormal spontaneous activity and decreased motor nerve conduction velocities can be found if there is concurrent peripheral neuropathy. Serum concentrations of CK and AST are generally normal. Other systemic manifestations of hypothyroidism may or may not be present.

At necropsy, overall muscle atrophy can be seen. Thyroid glands are often bilaterally atrophied, and megaesophagus can be present. Symmetric alopecia (endocrine dermatopathy) can also be seen. Type 2 myofibers are preferentially atrophied. Axonal degeneration can occur in peripheral nerves and can lead to angular atrophy of both type I and type II fibers because of denervation, and to fiber-type grouping as a result of reinnervation.

1029

1030

Diagnosis is suspected on the basis of clinical findings and selective type 2 atrophy or evidence of denervation or reinnervation in affected muscles but should be confirmed by evaluation of thyroid function. In many cases, replacement thyroid hormone will improve the signs of neuromuscular weakness.

15.2.2.5.3.2

#### Hypercortisolism

This disorder can occur because of either increased adrenocortical cortisol production or administration of exogenous corticosteroids. Clinical findings of neuromuscular weakness can be very similar to those in hypothyroidism. A unique manifestation of hypercortisolism in some dogs is development of a remarkably stiff, stilted pelvic limb gait, with increased bulk and tone of proximal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

thigh muscles (Cushingoid pseudomyotonia). The cause of Cushingoid pseudomyotonia is not known, although induction of sarcolemmal ionic instability is postulated. Concentric needle electromyography of these muscles reveals myotonic bursts that do not wax and wane (pseudomyotonic activity). Muscles do not dimple after percussion. Other systemic signs of hypercortisolism such as symmetric muscle atrophy and alopecia can also be present. Serum concentrations of CK and AST are normal. Adrenal glands have bilateral cortical atrophy due to exogenous corticosteroid administration or bilateral hypertrophy due to stimulation secondary to pituitary neoplasia. Adrenal cortical neoplasia causes enlargement of the affected gland and atrophy of the contralateral gland. Findings in affected muscle and peripheral nerves are similar to those seen in hypothyroid myopathy (i.e., selective type 2 fiber atrophy) and evidence of axonal degeneration in peripheral nerves, type 1 and type 2 fiber atrophy indicative of denervation atrophy, and fiber-type grouping reflecting reinnervation are possible (Fig. 15-24, B).

Diagnosis is suspected on the basis of clinical and histopathologic findings but should be confirmed by evaluation of adrenocortical function and total serum cortisol. Cessation of exogenous corticosteroids, removal of adrenal neoplasia, or chemical destruction of hyperplastic adrenal cortical tissue results in improvement in muscle mass and strength, although signs of pseudomyotonia may persist.

### 15.2.2.5.4 Immune-Mediated Myopathies (Listed in Table 15-9)

#### 15.2.2.5.4.1 Polymyositis

Polymyositis is due to immune-mediated inflammation that attacks components of the skeletal myofibers and results in myofiber necrosis (Fig. 15-32). The immunologic injury can be directed against skeletal muscle only or can be part of a more generalized immune-mediated disease, such as systemic lupus erythematosus. Polymyositis can also occur in dogs with thymoma. This generalized inflammatory myopathy can have an acute and rapidly progressive course or an insidious onset of muscle atrophy and generalized weakness. Temporal and masseter muscle atrophy may be most obvious, mimicking the appearance of dogs with masticatory myositis (see later discussion). Esophageal muscle involvement can lead to esophageal fibrosis and esophageal dysfunction, including megaesophagus. Respiratory muscle involvement can occur and, if severe, will cause respiratory distress. Pain on palpation of muscles is rare. Serum concentrations of CK, AST, and ALT can be increased, but in chronic cases these concentrations can also be within normal limits. Concentric needle electromyography often reveals scattered foci of abnormal spontaneous activity, and motor nerve conduction velocities are normal.

At necropsy, overall muscle atrophy may be the only finding. Aspiration pneumonia can occur secondary to megaesophagus. Histologic findings within affected muscles are extremely variable. In acute, fulminating cases, the muscle sections are filled with inflammatory cells, predominantly lymphocytes and plasma cells (Fig. 15-52, A), although eosinophils and neutrophils can also be present. The degree of myofiber necrosis is variable. Necrotic fibers in early stages will have a rim of lymphocytes that can be seen to invade intact myofibers (Fig. 15-32, B). Necrosis is followed by regeneration, but basal lamina damage is common and will result in some degree of healing by fibrosis. In more chronic and insidious cases, the only lesion consists of scattered lymphocytes adjacent to myofibers, with a variable degree of fibrosis and chronic myopathic change (Fig. 15-52, B). Sampling multiple muscles for histopathologic examination is recommended.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Polymyositis should be suspected based on the clinical findings, but identification of characteristic changes within muscle sections is often necessary to confirm the diagnosis. A positive circulating antinuclear antibody titer (ANA) is useful but is not always found. Treatment with immunosuppressive drugs such as corticosteroids can be curative, but affected animals may require lifelong therapy.

15.2.2.5.4.2

### Masticatory myositis (eosinophilic myositis; atrophic myositis)

The type 2 myofibers in the masticatory muscles of the dog contain a unique myosin isoform (type 2M myosin). On occasions, antibodies to this myosin form, and the result is an inflammatory myopathy confined to the temporalis and masseter muscles. Severe, acute cases display bilaterally symmetric swelling of and pain in those muscles and an inability to fully open the jaw. Affected dogs can have difficulty prehending food. More chronic or insidious cases have bilaterally symmetric atrophy of the temporal and masseter muscles ([Fig. 15-53](#)) and decreased jaw mobility. Pain may or may not be evident at this stage. Concentric needle EMG often reveals foci of spontaneous activity in active cases, but can be normal in more chronic cases. Serum concentrations of CK and AST are normal or only mildly increased.

1030

Fuhrer, *Clinic Veterinaire de St. Avertin, France*. **B**, Courtesy Dr. B.A. Valentine, *College of Veterinary Medicine, Oregon State University*.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Severely atrophied muscles often contain pale streaks. The degree and nature of the inflammation are variable. In acute cases, infiltrates of lymphocytes and plasma cells, similar to those in polymyositis, are present. There can also be numerous eosinophils, and eosinophils can be the predominant cell type. Neutrophils are much less common. Inflammation is associated with myofiber necrosis. Regeneration can restore myofibers, but because the basal lamina is often damaged, development of fibrosis is common. The presence of fibrosis is an important prognostic indicator because fibrosis is an irreversible change.

**Fig. 15-53 Chronic masticatory myositis, skeletal muscle, dog.** Note the severe atrophy of the temporalis and masseter muscles. (Courtesy Dr. W. Hornbuckle, College of Veterinary Medicine, Cornell University.)

The diagnosis is suggested on the basis of characteristic clinical findings. Masticatory myositis must be differentiated from polymyositis, which can also have severe involvement of the temporal and masseter muscles. Serologic testing to detect anti-type 2M myosin antibodies specific to masticatory muscle myositis is available, and serum from affected dogs will bind to type 2M fibers (Fig. 15-54). Electromyography and histopathologic evaluation of multiple muscles can also help to differentiate these two disorders. Treatment with immunosuppressive doses of corticosteroids generally alleviates pain and results in increased mobility of the jaw and increase in muscle mass. Some degree of atrophy and loss of complete jaw mobility can persist. A single course of corticosteroids can be curative; however, some cases require extended therapy.

1031

1032

**Fig. 15-54 Canine masticatory myositis, skeletal muscle, temporalis muscle, transverse sections, normal dog.** **A**, A single type 1 fiber (*light staining, M*) surrounded by type 2 fibers (*dark staining*). Frozen section, ATPase pH 9.8. **B**, After incubation with serum from a dog with masticatory myositis, type 2 fibers stain positively because of binding of anti-type 2M myosin antibodies from the affected dog. Notice that the type 1 fiber (*M*) is unstained. Frozen section, staphylococcal protein A-peroxidase. (*A and B, Courtesy Dr. G. D. Shelton, University of California, San Diego.*)

### 15.2.2.5.4.3

#### Extraocular muscle myositis

An immune-mediated attack directed specifically at extraocular muscles is the suspected cause of this disorder. Acute onset of bilateral exophthalmos is seen. Affected dogs are usually less than 2 years of age, and golden retriever dogs appear to be predisposed. Serum concentrations of CK and AST are generally normal.

The extraocular muscles, with the exception of the retractor bulbi muscle, are swollen and pale yellow. A predominantly lymphocytic inflammation resulting in myofiber necrosis and regeneration is seen. Because it is difficult to obtain a biopsy sample of the extraocular muscles, diagnosis is generally based on typical clinical findings. Corticosteroid therapy is effective, but episodes can recur.

### 15.2.2.5.5

#### Disorders of the Neuromuscular Junction

### 15.2.2.5.5.1

#### Myasthenia gravis

The pathogenesis of myasthenia gravis is discussed in the section on neuropathic and neuromuscular junction disorders ([Fig. 15-33](#)). In most cases, myasthenia gravis is an acquired disease, with circulating antibodies directed at the acetylcholine receptors of the neuromuscular junction. An

## Pathologic Basis of Veterinary Disease, 4th Edition

---

inherited predisposition to development of acquired myasthenia gravis has been reported in Newfoundland dogs. In some cases, onset of myasthenia gravis occurs because of thymoma or, less commonly, thymic hyperplasia. Congenital myasthenia gravis is due to abnormal development of the neuromuscular junction and is inherited as an autosomal recessive trait in Jack Russell terriers, smooth fox terriers, and Springer spaniels. Congenital myasthenia gravis also occurs in smooth-haired miniature dachshunds. Typical signs of acquired disease are episodic collapse in an adult dog, with normal gait and strength after rest. Clinical signs can, however, be variable. The canine esophagus contains a large percentage of skeletal muscle in its wall; therefore megaesophagus is common in dogs with myasthenia gravis and may be the only presenting sign. In some cases, mild weakness persists between episodes. Clinical signs of congenital myasthenia gravis appear at an early age (6 to 8 weeks of age) and in most affected breeds are progressive and typically quite severe. Affected dachshunds, however, appear to recover by 6 months of age. Repetitive motor nerve stimulation reveals an initial sharp decremental response, followed by relatively uniform amplitude potentials. Serum concentrations of CK and AST are normal.

No findings are evident at postmortem examination unless megaesophagus or thymic abnormalities are present, and no abnormalities in muscle are seen on light microscopic examination. Ultrastructural abnormalities of the neuromuscular junctions (simplification of the postsynaptic membrane) can be seen.

Diagnosis is suspected on the basis of typical clinical findings and results of repetitive nerve stimulation. In patients with acquired myasthenia gravis, dramatic transient improvement in muscle strength following administration of intravenous acetylcholinesterase inhibitors such as edrophonium (Tensilon) will be seen, and the diagnosis is confirmed by identification of circulating antibodies to skeletal muscle acetylcholine receptors. In cases of acquired myasthenia gravis, the presence of thymic abnormalities should be determined, as removal of a thymoma or of a hyperplastic thymus results in resolution of clinical signs. In other cases, long-acting acetylcholinesterase inhibitor therapy, sometimes combined with corticosteroid therapy, is often beneficial. There is no effective treatment for congenital myasthenia gravis.

### 15.2.2.5.5.2

#### Tick paralysis

In a dog with flaccid tetraparesis, a diagnosis of tick paralysis should be considered along with polyradiculoneuritis (coonhound paralysis; See Disorders of Peripheral Nerves) and botulism. Clinical signs of tick paralysis appear 5 to 7 days following infestation with causative *Dermacentor* or *Ixodes* ticks. Initial clinical signs are of pelvic limb weakness, with progression to recumbency within 48 to 72 hours. Cranial nerve function is normal. Clinical signs of tick paralysis are very similar to those of coonhound paralysis (see peripheral nerve discussion). Treatment for tick infestation can result in recovery within a few days, although death due to respiratory muscle paralysis is still possible.

### 15.2.2.5.5.3

#### Botulism

Botulism occurs in dogs, resulting in rapid onset of flaccid tetraparesis, but is rare. Reported cases of canine botulism are most often due to types C and D of *Clostridium botulinum* neurotoxins. Diagnosis is often presumptive, based on a failure to identify other causes of diffuse neuromuscular weakness and, with luck, a history of consumption of a rotted carcass. Recovery has been reported in dogs with botulism, although many cases are fatal.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

15.2.2.5.6	Other Canine Myopathies	
15.2.2.5.6.1	Exertional rhabdomyolysis	
	Massive acute rhabdomyolysis associated with exertion occurs in racing greyhounds and sled dogs. Muscles of the back (longissimus) and thigh (gluteal) are most often affected and may be severely swollen. Predisposing factors are not clear, but in sled dogs a change to a very high-fat diet has resulted in decreased exercise-induced muscle injury.	1032 1033
15.2.2.5.6.2	Malignant hyperthermia	
	Malignant hyperthermia occurs sporadically in dogs, and breeding studies indicate an autosomal dominant inheritance. The cause has been determined to be a genetic defect in the muscle ryanodine receptor, which is also the cause of malignant hyperthermia in pigs and human beings. Malignant hyperthermia–like episodes can also occur in any dog following ingestion of hops used for brewing beer.	
15.2.2.5.6.3	Other breed-specific myopathies	
	A number of breed-specific myopathies have been reported in the dog, including dermatomyositis in collies and Shetland sheepdogs, mitochondrial myopathy in Old English sheepdogs and other breeds, and myopathy of Bouvier des Flandres dogs, English Springer spaniels, and rottweilers. Myoclonus and intramuscular La Forra-like bodies occur in wirehaired miniature dachshunds. These are discussed in more detail in <a href="#">Appendix 15-1</a> .	
15.2.2.5.7	Idiopathic Masticatory Muscle Atrophy	
	Dogs can develop a progressive atrophy of temporal and masseter muscles that is not associated with pain or difficulty opening the jaw or prehending food. Examination of affected muscle from these dogs reveals mild generalized atrophy of myofibers, but there is no evidence of inflammation, degeneration, fibrosis, or denervation. The cause is not known, and there is no treatment.	
15.2.2.5.8	Denervating Diseases	
	There are numerous causes of inherited and acquired peripheral nerve disorders causing axonal damage and resultant denervation in dogs (see Disorders of the Peripheral Nervous System). Motor neuron disease is most often inherited, such as in the Brittany spaniel and rottweiler. Such disorders cause symmetric atrophy of affected muscle. Neoplasms arising in peripheral nerves (nerve sheath neoplasms) cause compression of the nerve and axonal degeneration and loss, leading to progressive gait abnormalities and ultimately denervation atrophy of muscles of the affected limb.	

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.2.2.6 MUSCULAR DISORDERS OF THE CAT

Relatively few muscular disorders have thus far been identified in cats. This may, in part, be due to the low performance expectations of the average house cat. It is entirely possible that there are many cats lying around with muscular disorders that have, as yet, gone unrecognized.

#### 15.2.2.6.1 Inherited or Congenital Myopathies

##### 15.2.2.6.1.1 X-linked muscular dystrophy (Duchenne's type)

Dystrophic cats lack the muscle cytoskeletal protein dystrophin, which is also the cause of Duchenne's dystrophy in boys and X-linked muscle dystrophy in the dog. Affected cats develop a progressive, persistent, stiff gait associated with marked muscular hypertrophy. The cause of the remarkable muscular hypertrophy seen in affected cats, as opposed to the muscle atrophy seen in the dog and in human beings, and the pseudohypertrophy as a result of fat infiltration that can occur in human beings, is not known. Age of onset is from a few months to 21 months of age. Affected cats have difficulty grooming, jumping, and lying down. Concentric needle EMG reveals dense and sustained abnormal spontaneous activity, similar to findings in the dystrophic dog. Serum concentrations of CK, AST, and ALT are elevated, typically to very high levels. Affected cats can die under anesthesia or following restraint or sedation because of a malignant hyperthermia-like syndrome.

At necropsy, all muscles are severely hypertrophied and may contain pale areas. Focal pale or chalky areas within the myocardium are typically found. Histologically, muscles show a range of changes. Concurrent segmental myonecrosis and myofiber regeneration (polyphasic necrosis) are characteristic. Chronic myopathic changes, found in older animals, include severe myofiber hypertrophy, myofiber atrophy, internal nuclei, and mild to moderate endomysial fibrosis. Myocardial lesions consist of multifocal necrosis and mineralization of cardiac myofibers and fibrosis, primarily in the left ventricular free wall, papillary muscles, and septum. Affected cats may have a relatively normal life span, although unexpected death during anesthesia or forced restraint is common. The exact cause of this is unclear.

The diagnosis is suspected on the basis of characteristic clinical, clinicopathologic, and histopathologic findings in a young male cat. Confirmation relies on assay of muscle samples for dystrophin or on immunohistochemical staining for dystrophin in frozen sections.

##### 15.2.2.6.1.2 Other feline inherited or congenital myopathies

Glycogenosis type IV (glycogen branching enzyme defect) affecting skeletal muscle is seen as an inherited disorder in Norwegian Forest cats. A histologically similar condition occurs occasionally in other breeds. Feline nemaline myopathy is a rare congenital myopathy in the cat. A poorly understood condition that may be myopathic occurs in Devon Rex cats. These disorders are discussed in more detail in [Appendix 15-1](#).

1033

15.2.2.6.2

### Myopathies Due to Electrolyte Abnormalities (Hypokalemia and Hypernatremia)

Similar to cattle, cats with severe electrolyte abnormalities can show signs of neuromuscular weakness that can cause a degenerative myopathy. Although degenerative myopathy has been reported secondary to increased blood sodium concentrations (hypernatremia), hypokalemic myopathy occurs far more frequently.

The cause of the weakness and myofiber necrosis associated with electrolyte abnormalities is complex and involves abnormal skeletal muscle energy metabolism and possible ischemia because of vasoconstriction. Hypokalemia (potassium less than 3.5 mEq/L) can occur because of decreased dietary intake or increased urinary excretion of potassium. In cats, hypokalemia is often a consequence of chronic renal disease. It can also occur secondary to gastrointestinal disease or inappropriate fluid therapy. Hyperthyroidism has been associated with development of hypokalemic myopathy in cats. Hypernatremic myopathy is less common, but has been reported in a 7-month-old cat with hydrocephalus and transient hypopituitarism.

Affected cats show severe generalized weakness, with notable ventroflexion of the neck. Concentric needle EMG often demonstrates foci of abnormal spontaneous activity. Serum concentrations of CK, AST, and ALT are often increased, sometimes severely. Blood concentrations of potassium are low in hypokalemia, and blood concentrations of sodium are high in hypernatremia.

No specific gross pathologic findings are present except in cats with hypokalemia as a result of chronic renal disease, in which the kidneys are small and fibrotic. In hypokalemic myopathy, myofiber necrosis and regeneration of variable severity are present concurrently (polyphasic necrosis). If renal disease is present, chronic interstitial nephritis is most commonly seen. No abnormalities were detected in a muscle biopsy from the cat with hypernatremic myopathy, although the mildly increased serum concentration of creatine kinase and abnormal EMG suggest mild and perhaps transient myofiber necrosis and regeneration.

Diagnosis is based on characteristic clinical findings of weakness and concurrent hypokalemia or hypernatremia. Treatment of affected cats has been very successful. Immediate fluid therapy is used to correct the electrolyte abnormality, followed by diet change to maintain normal electrolyte concentrations. If there is an underlying hyperthyroidism, this should also be treated.

15.2.2.6.3

### Immune-Mediated Disorders

An immune-mediated myositis has been described in cats infected with feline immunodeficiency virus. Serum concentration of CK is moderately increased, but clinical signs of muscle dysfunction are not apparent. Infiltration of muscle by CD8<sup>+</sup> lymphocytes, similar to HIV-associated polymyositis in human beings, is characteristic.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 15.2.2.6.4 Disorders of the Neuromuscular Junction

#### 15.2.2.6.4.1 Myasthenia gravis

Feline acquired and congenital myasthenia gravis are similar to these disorders in the dog but occur less commonly.

#### 15.2.2.6.4.2 Botulism

Although theoretically possible, we are not aware of any confirmed or highly suspicious cases of botulism in cats. This likely reflects both inherent resistance to botulinum toxin and the typical feline fastidious appetite.

#### 15.2.2.6.5 Denervating Diseases

Disorders affecting peripheral motor nerves are much less common in cats as compared with dogs. A chronic relapsing polyneuritis primarily affecting ventral spinal roots has been seen in young adult cats, which can cause denervation atrophy in affected muscles. Diabetes mellitus can also result in peripheral neuropathy in cats.

### 15.4 APPENDIX 15-1

#### 15.4.1 VIRAL CAUSES OF MYOSITIS

Porcine encephalomyelitis is caused by a coronavirus of the *Enterovirus* genus. Besides the destruction of the neurons, which results in paralysis, the virus can also cause multifocal necrosis of myofibers, accompanied by a focal interstitial and perivascular infiltrate of lymphocytes, macrophages, and a few neutrophils.

The major lesions of foot and mouth disease virus in ruminants and pigs are vesicles in the skin and mucous membranes. In addition, the heart and skeletal muscles can have yellow streaks and pale foci, which microscopically are areas of segmental myofiber necrosis accompanied by an intense lymphocytic and neutrophilic infiltration.

Akabane virus (Bunyaviridae family) can produce a nonsuppurative myositis in the bovine fetus.

Bluetongue, caused by a virus of the family Reoviridae, is a noncontagious, insect-borne viral disease of sheep that causes vasculitis in a wide array of tissue, particularly the oral mucosa. Gross lesions in muscles are foci of necrosis (infarctions) and hemorrhage. Depending on the age of the lesions, necrosis, calcification, or regeneration may be present. Because of the size of the infarcts, regeneration is usually not possible, and healing is by fibrosis.

#### 15.4.2 PARASITIC MYOSITIDES

The larval forms of *Ancylostoma caninum* migrate somatically, primarily in human beings. After entering the muscles of paratenic hosts, development is arrested. The larvae cause inflammation and myonecrosis. As they continue to migrate, they leave a trail of inflammation and segmental myofiber necrosis.

*Toxocara canis* larvae migrate through numerous tissues of the dog (visceral larval migrans). Some larvae are arrested, and granulomas form around them. These have been found in a wide array of tissue, including kidney, liver, lung, myocardium, and skeletal muscle. The lesion in muscle is a focal granulomatous myositis, with the larvae and granulomas lying between myofibers.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Dirofilaria immitis*, a nematode normally found in the hearts of dogs and cats, can occasionally involve the external and internal iliac arteries and their branches. Thromboemboli from debris and parasites can cause multiple infarcts in the muscles of the hindlimbs (see Disturbance of Circulation).

Cysticercus is a larva with a solid caudal portion and a bladderlike proximal portion. It is the intermediate stage in the life cycle of several tapeworms. *Taenia solium* and *Taenia saginata*, both tapeworms of human beings, have a cysticercus stage in the pig (*Cysticercus cellulosae*) and cattle (*Cysticercus bovis*). These cysticerci preferentially lodge in the most active muscles, especially the heart, masseter, diaphragm, and tongue, where they appear as small white or gray cysts. Histologically, there is displacement of myofibers by the cyst, but little myositis; there may be a few lymphocytes, macrophages, and eosinophils around the cyst, which lies in the interstitial tissue, not within the myofiber. With time, the immunologic system of the host kills the cysticercus. *Cysticercus cellulosae* in pigs can become calcified. *Cysticercus ovis* in the heart and shoulder muscles of sheep and goats is the intermediate stage of *Taenia ovis*, a tapeworm of dogs.

*Hepatozoon americanum* is a protozoal organism, previously classified as *Hepatozoon canis*, that infects multiple tissues, including the skeletal muscle of dogs. It is most common in South Africa and the Middle East, but also occurs in areas of the United States (primarily Oklahoma and the Gulf Coast area). Young dogs, up to 6 months of age, are most susceptible to infection. The organism is transmitted by ingestion of an infected tick, such as *Rhipicephalus sanguineus*. Sporozoites invade through the intestinal wall and travel to multiple tissues, particularly liver and skeletal muscle, where they undergo schizogony. Suppurative to granulomatous inflammation occurs following rupture of schizonts within tissue. Encysted stages, however, do not elicit an inflammatory response. Clinical signs include fever, anorexia, weight loss, body pain, and gait abnormalities. Respiratory signs can also occur. Serum CK activity is often mildly increased. Radiographs often reveal a characteristic periosteal proliferation of long bones similar to that of hypertrophic osteopathy. Diagnosis is made by identification of the organism either within peripheral neutrophils or within affected tissue. 1035 1036

In dogs, infection by *Trypanosoma cruzi* (Chagas' disease) causes myocarditis with lesser involvement of skeletal muscle. Inflammation consists of lymphocytes admixed with macrophages. Protozoal organisms are typically readily identified in affected tissues.

### 15.4.3 CONGENITAL AND INHERITED MYOPATHIES

#### 15.4.3.1 CONGENITAL MUSCULAR HYPERPLASIA (DOUBLE MUSCLING) IN CATTLE

This disorder is seen in several beef breeds, including Charolais, Angus, Belgian blue, Belgian white, South Devon, Santa Gertrudis, and Piedmontese cattle. This disorder is inherited as an autosomal recessive trait with incomplete penetrance. The genetic defect is inactivation of the myostatin gene, which regulates the number of myofibers. Affected calves have large, bulky muscles, especially of the shoulder and rump, because of an increased number of otherwise normal fibers. This increased muscle bulk predisposes to dystocia. Body fat deposits and intramuscular fat are reduced to about 60% of normal, which is considered desirable in a meat-producing animal. The diagnosis of this disorder is readily made based on typical clinical findings. There is no treatment.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.4.3.2 MUSCULAR DYSTROPHY

#### 15.4.3.2.1 BOVINE DIAPHRAGMATIC DYSTROPHY

A muscular dystrophy affecting diaphragm and respiratory muscles has been recognized in Meuse-Rhine-Yssel cattle in Europe and Holstein cattle in Japan. This disorder appears to be inherited as an autosomal recessive trait. The most common clinical sign is recurrent bloat. Clinical signs appear in adults 2 years of age or older and include loss of condition, decreased rumen activity, and recurrent bloat. Serum activity of muscle enzymes is normal. The diaphragm is found to be thickened and pale. Examination of affected muscle indicates a progressive myopathy with severe cytoarchitectural alterations and other chronic myopathic changes, including fibrosis. Scattered necrotic fibers can be found, but this myopathy does not have the characteristic ongoing progressive myofiber necrosis and regeneration of muscular dystrophy. Central corelike lesions are prominent and have been found to contain actin and ubiquitin with immunohistochemical studies. This disorder would be best defined as a progressive inherited myopathy, possibly a myofibrillar myopathy. There is no treatment, and animals producing affected offspring should not be rebred.

#### 15.4.3.2.2 OVINE MUSCULAR DYSTROPHY

A progressive disorder known as ovine muscular dystrophy is recognized in Merino sheep in Australia. The underlying defect is not known. The disease is inherited as an autosomal recessive trait. Clinical signs of neuromuscular weakness occur as early as 1 month of age and are characterized by a stiff gait and exercise intolerance. Serum concentrations of CK and AST are increased. Because the disease affects only type 1 myofibers, gross lesions are most easily seen in muscles that consist primarily or only of type 1 myofibers (e.g., vastus intermedius). The appearance depends on the age of the animal. Initially the muscle is pale and lacks tone but is close to normal size. In the next few years, the muscle becomes firm, more atrophic, and pale gray to almost white as the space formerly occupied by the myofibers is filled with adipocytes and fibrosis. There is atrophy and hypertrophy of the myofibers, along with myopathic features, such as internal nuclei and subsarcolemmal masses. Lesions do not have the characteristic ongoing progressive myofiber necrosis and regeneration of muscular dystrophy, and this disorder may be best defined as a progressive inherited myopathy. Diagnosis is based on characteristic clinical and histopathologic findings. There is no treatment for this progressive disorder, and animals producing affected lambs should not be rebred.

#### 15.4.3.2.3 OTHER CANINE MUSCULAR DYSTROPHIES

Defects in sarcoglycan, a protein that is part of the sarcolemmal dystrophin glycoprotein complex, have been found in both male and female dogs of various breeds. Affected dogs exhibit signs of neuromuscular disease by 1 year of age. Serum activities of CK, AST, and ALT are increased. Electromyography detects abnormal spontaneous activity, including myotonic bursts, and histopathologic findings of multifocal polyphasic necrosis are consistent with muscular dystrophy.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.4.3.3 OTHER MUSCULAR DISORDERS OF CATTLE

#### 15.4.3.3.1 MYOPATHY OF GELBVIEH CATTLE

A necrotizing myopathy of juvenile Gelbvieh cattle has been recognized. An inherited basis is suspected.

1036

Clinical signs include neuromuscular weakness. The characteristic histopathologic change in affected muscles is necrotizing vasculitis that results in myofiber necrosis. The pathogenesis of this disorder is not known; both vitamin E deficiency and immune-mediated disease have been suggested. Pathologic changes are also found in the kidney, dorsal spinal tracts of the spinal cord, and in peripheral nerves. Cardiac lesions can occur but are uncommon. Treatment with vitamin E may be of some benefit.

1037

#### 15.4.3.3.2 BROWN SWISS CATTLE NEURONOPATHY

An inherited neuronal degenerative disease designated as a form of spinal muscular atrophy occurs in brown Swiss cattle. Clinical signs of a progressive lower motor neuron weakness appear by 2 to 6 weeks of age. Neuronal degeneration within the ventral gray matter of the spinal cord leads to axonal degeneration of peripheral nerves and denervation atrophy of muscle. The disorder is inherited as an autosomal recessive trait, and pedigree analysis has identified a common ancestor thought to be the founder animal. Animals producing affected calves should not be rebred.

### 15.4.4 OTHER BREED-ASSOCIATED DISORDERS OF DOGS

#### 15.4.4.1 CANINE DERMATOMYOSITIS

A condition involving skin and muscle has been described in collies and Shetland sheepdogs, and has been compared with dermatomyositis of human beings. In human beings, characteristic skin lesions and immune-mediated damage to muscle capillaries occur. In dogs, the dermatopathologic changes are distinctive, but muscle involvement is much less common, and the muscle lesions seen are not always convincingly vascular in nature. In cases studied by one of the authors, occasional muscle inflammation appeared to reflect extension of inflammation from overlying ulcerated skin.

#### 15.4.4.2 MYOPATHY OF BOUVIER DES FLANDRES DOGS

A progressive degenerative myopathy affecting males and females is recognized in Bouvier des Flandres dogs. Onset of clinical signs of neuromuscular weakness varies from about 2 months to 2 years of age. Esophageal and pharyngeal muscles are often most severely affected. Generalized muscle atrophy, weakness, and abnormal gait are typical. Serum activities of CK and AST are often moderately increased. Electromyography reveals abnormal spontaneous activity (myotonic bursts). Generalized muscle atrophy and megaesophagus are common necropsy findings. Histopathologic changes are generally severe chronic myopathic change with notable cytoarchitectural changes. Multifocal fiber necrosis and regeneration occurs but is not common. Cardiac necrosis and fibrosis can also be seen.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 15.4.4.3 DISTAL MYOPATHY OF ROTTWEILER DOGS

Both males and females are affected. Clinical signs of progressive muscle weakness and development of a plantigrade and palmigrade stance are apparent by about 2 months of age. This disorder is characterized histologically by severe fiber atrophy and fat infiltration, primarily of distal limb musculature. Myonecrosis and fibrosis are mild. Serum activities of CK and AST can be normal or slightly increased. Electromyography reveals rare spontaneous activity (fibrillations and positive sharp waves). Decreased serum and muscle carnitine concentrations suggest that this may be a lipid metabolic disorder.

### 15.4.4.4 MYOPATHY OF ENGLISH SPRINGER SPANIELS

A myopathy with involvement of esophageal muscle occurs in English springer spaniel dogs. Affected dogs also have dyserythropoiesis and cardiomegaly. Histologic findings are of chronic myopathic change with central linear or granular inclusions within myofibers.

### 15.4.4.5 MYOCLONUS IN WIREHAired MINIATURE DACHSHUNDS

A syndrome of sustained muscle contraction (myoclonus), seizures, and early dementia is recognized in related wirehaired miniature dachshunds. Inclusions of PAS-positive, amylase-resistant polyglucosan bodies similar to La Fora bodies described in human beings occur in skeletal muscle and central nervous tissue.

### 15.4.5 OTHER BREED-ASSOCIATED DISORDERS OF CATS

Feline nemaline myopathy is a congenital disorder described in domestic short-haired cats. Affected cats develop a characteristic progressive gait abnormality and muscle atrophy at an early age. The characteristic pathologic finding of expanded Z-line material (nemaline rods) within skeletal muscle fibers is only apparent in frozen sections or ultrastructurally. The mode of inheritance is not known.

A congenital disorder resulting in spasticity has also been described in Devon Rex cats. At this time it is not known if this is truly a myopathic disorder, nor has the mode of inheritance been determined.

1037

1038

### 15.4.6 MYOTONIA

#### 15.4.6.1 EQUINE SPECIES

Congenital or early-onset myotonia is seen in thoroughbreds, standardbreds, and quarter horses. Various similar disorders, designated as myotonic dystrophy-like or muscular dystrophy-like, are likely to be the same or similar disorders. As with all congenital myotonias, an underlying abnormal ion channel leading to continuous abnormal muscle activity is suspected. But to-date the defect and potential for inheritance have not been defined. Affected horses have remarkable exercise intolerance, with stiffness of posture and gait apparent at birth or soon thereafter, and often, remarkably well-defined to hypertrophied muscle groups. Clinical signs of stiffness are most apparent when the animals first begin to move, with some decrease in stiffness with exercise. Serum concentrations of CK and AST are generally normal to only slightly increased. Muscles often show prolonged dimpling after percussion. Concentric needle electromyography demonstrates characteristic waxing and waning ("dive bomber") myotonic bursts.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

No specific gross lesions are present, other than prominent muscling. On histologic examination, affected muscle fibers vary tremendously in size and shape, with numerous internal nuclei, altered cytoplasmic areas beneath the sarcolemma (sarcoplasmic masses), and other cytoarchitectural alterations, such as ring fibers. Scattered fiber necrosis and regeneration may be seen, but is not a prominent feature. In chronic cases, affected muscles can develop a variable degree of replacement of myofibers by fat, indicating a previous loss of myofibers.

The diagnosis of myotonia is based on characteristic clinical signs in a young horse and can be confirmed by electromyography or muscle biopsy. No specific treatment is known at this time.

### 15.4.6.2 FELINE SPECIES

The pathogenesis of feline congenital myotonia is not known at this time, although a skeletal muscle ion channel defect is suspected. Cats with congenital myotonia have signs similar to those of cats with X-linked muscular dystrophy, but the muscular hypertrophy is less remarkable. A stiff gait is the most obvious sign. Serum concentrations of CK and AST are normal or only slightly increased. Concentric needle electromyography reveals waxing and waning (“dive bomber”) potentials characteristic of myotonia. Other than mild muscular hypertrophy, there are no findings at necropsy. Significant myofiber hypertrophy and increased variation in myofiber diameter are the only histopathologic findings. Dilation of sarcotubular elements is the characteristic ultrastructural finding. The diagnosis of congenital feline myotonia is based on characteristic clinical findings. At this time, no type of treatment has been attempted.

### 15.4.7 METABOLIC MYOPATHIES

#### 15.4.7.1 ACID MALTASE DEFICIENCY (GLYCOGENOSIS TYPE II; POMPE'S DISEASE)

This defect has been described in shorthorn and Brahman cattle and is inherited as an autosomal recessive trait. The enzyme defect results in blockage of the glycolytic metabolic pathway and in cellular dysfunction, which is most evident in skeletal muscle, Purkinje cells of the heart, and neurons. Myofiber necrosis is thought to be a result of a cellular “energy crisis” (i.e., energy deprivation).

Affected shorthorn cattle often show clinical signs of weakness by 3 to 7 months of age and die as a result of respiratory and cardiac failure. Affected shorthorn cattle may also develop relatively normally until 1 to 1½ years of age, at which time weakness and neurologic deficits are evident. Affected Brahman cattle grow poorly and have muscular weakness and neurologic disease. Electrocardiographic studies reveal abnormalities of cardiac conduction. Serum concentrations of CK and AST can be increased, with notable increases evident in severely weak animals before death.

There may be no obvious changes within the skeletal and cardiac muscle at necropsy, although pale streaks may be evident in those animals undergoing myofiber necrosis before death. No gross pathologic lesions are evident in the nervous system. On histopathologic examination, affected myofibers, cardiac myocytes, and neurons are filled with vacuoles containing glycogen (vacuolar myopathy and neuronopathy), which can be demonstrated by PAS reaction. Glycogen accumulation in skeletal myofibers is segmental, whereas in neurons it is diffuse. Both degeneration and regeneration of skeletal muscle fibers and chronic myopathic change (fiber atrophy, hypertrophy, and internal nuclei) are present.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Diagnosis of a glycogenosis can be made based on characteristic clinical and histopathologic findings. Assay of affected tissue for glycolytic enzyme activities is necessary to determine the specific enzyme defect. There is no effective treatment for this disorder, and cattle known to produce affected calves should not be rebred.

1038

15.4.7.2

### MYOPHOSPHORYLASE DEFICIENCY (GLYCOGENOSIS TYPE V; MCARDLE DISEASE)

1039

This disorder has been identified in Charolais cattle. Myophosphorylase deficiency is an autosomal recessive disorder with glycogen storage similar to acid maltase deficiency, but with only skeletal muscle involvement. Clinical signs of exercise intolerance and inability to keep up with herd mates are recognized at a relatively early age. If forced to exercise, affected cattle become recumbent for up to 10 minutes. Serum concentrations of CK and AST are often mildly to markedly increased. No specific findings are evident at necropsy. Histopathologic findings in skeletal muscle are similar to those of acid maltase deficiency. Diagnosis can be based on characteristic clinical and histopathologic findings. Affected animals and carriers can be detected after analysis of peripheral blood leukocyte DNA by polymerase chain reaction assay. There is no treatment, and carrier animals should not be used for breeding.

A glycogen storage myopathy due to myophosphorylase deficiency has been identified in sheep in Australia and is similar to the disease in cattle.

15.4.7.3

### PHOSPHOFRUCTOKINASE DEFICIENCY (GLYCOGENOSIS TYPE VII)

This is an autosomal recessive disorder in dogs caused by a point mutation in the muscle isoenzyme of phosphofructokinase, an important enzyme in the glycolytic pathway. This disorder has been recognized in English springer spaniels and American cocker spaniels. Muscles from older affected dogs can have myopathic changes and inclusions of a PAS-positive, amylase-resistant substance classified as complex polysaccharide. Clinical signs of neuromuscular dysfunction do not occur, however, because skeletal muscle up-regulates expression of the liver isoenzyme of phosphofructokinase. Absence of erythrocyte phosphofructokinase results in hemolysis during periods of increased respiratory activity (panting) and resultant mild respiratory alkalosis.

15.4.7.4

### FELINE GLYCOGENOSES

Glycogenosis type IV occurs in Norwegian Forest cats because of decreased activity of glycogen branching enzyme (GBE), resulting in defective carbohydrate metabolism and a generalized glycogen storage disease. The disorder is inherited as an autosomal recessive trait. Affected cats may be stillborn or die within a few hours of birth. Those that survive lack energy and develop muscle tremors and a bunny-hopping pelvic limb gait at about 5 months of age. The disease is progressive, resulting in severe generalized muscle atrophy and tetraplegia. Concentric needle EMG reveals abnormal spontaneous activity with normal motor nerve conduction velocities. Serum concentrations of CK and AST are mildly to moderately increased. Muscle atrophy and fibrosis are evident in affected pelvic limb muscles of cats surviving 1 year or longer. Storage of PAS-positive, amylase-resistant material forming “lakes” within skeletal muscle fibers is the characteristic histopathologic finding. Myofiber atrophy is also prominent, and myofiber necrosis and regeneration can be seen. Cardiac myocytes have similar inclusions and undergo necrosis and replacement by fibrosis. Abnormal glycogen storage is also seen within smooth muscle and neurons in the central nervous system. Diagnosis can be suspected on the basis of characteristic clinical and histopathologic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

findings. Confirmation is based on assay of GBE concentration in blood leukocytes. There is no treatment for this disorder.

Similar intramyofiber inclusions of PAS-positive, amylase-resistant inclusions resulting in clinical signs of neuromuscular weakness are found rarely in older cats of mixed breeding, suggesting that there is more than one cause for this finding in cats.

### 15.4.7.5 EQUINE MITOCHONDRIAL MYOPATHY

A single case of mitochondrial myopathy in a 3-year-old Arabian filly has been reported. Deficiency of mitochondrial respiratory chain complex I was detected. Clinical signs were stiff gait and profound exercise intolerance. Lactic acidosis developed with minimal exercise. Skeletal muscle samples exhibited increased muscle mitochondrial content with bizarre cristae formation on ultrastructural examination.

### 15.4.7.6 CANINE MITOCHONDRIAL MYOPATHIES

A mitochondrial myopathy has been recognized in Old English sheepdogs. Clinical signs are exercise intolerance leading to episodic weakness and exercise-induced lactic acidosis. A suspected mitochondrial myopathy occurs in Welsh terrier dogs. Involvement of skeletal muscle occurs in Alaskan husky and Australian cattle dogs as part of a mitochondrial encephalomyopathy syndrome.

### 15.4.7.7 OTHER CANINE METABOLIC MYOPATHIES

Pyruvate dehydrogenase deficiency occurs in Clumber and Sussex spaniels in the United States and Belgium. Clinical signs are profound exercise intolerance with exercise-induced lactic acidosis. No gross or histopathologic lesions are found in muscle.

## 16 Chapter 16 Bone and Joints

STEVEN E. WEISBRODE

### 16.1 INTRODUCTION

The skeleton consists of bones and joints and is responsible for supporting and protecting the body and enabling movement initiated by the nervous system and moved by muscles. The skeleton can be divided into axial skeleton (head, vertebrae, ribs, and sternum) and appendicular skeleton (thoracic and pelvic limbs). The postmortem examination and evaluation of the skeleton is presented in the appendix at the end of the chapter ([Appendix 16-1](#)).

### 16.1.1 NORMAL STRUCTURE AND FUNCTION OF BONE

#### 16.1.1.1 BONE AT THE CELLULAR LEVEL

Structure and function can be discussed at the organ, tissue, and cellular levels. In this section, normal structure and function are briefly reviewed beginning at the cellular level and include bone matrix and mineral. Cells directly involved with the structural integrity of bone include osteoblasts, osteocytes, and osteoclasts ([Box 16-1](#)).

Osteoblasts are cells on any bone surface (periosteal, endosteal, trabecular, intracortical) that produce bone matrix (osteoid), initiate the mineralization of this matrix (deposition of hydroxyapatite), and seemingly paradoxically initiate the resorption of this matrix by osteoclasts. Osteoblasts are derived from mesenchymal stem cells. Active osteoblasts are plump ([Fig. 16-1](#)), with abundant basophilic cytoplasm rich in rough endoplasmic reticulum, prominent Golgi apparatus, and numerous mitochondria ([Fig. 16-2](#)). Inactive osteoblasts are disk-shaped with little cytoplasm because of the reduction in organelles needed for matrix synthesis and secretion ([Figs. 16-3 and 16-4](#)). Osteoblasts likely interact with osteocytes to assist in fine control of calcium homeostasis and detection of mechanical use and microscopic damage to bone as discussed later. An indirect measurement of osteoblast activity is reflected in blood concentrations of the enzyme alkaline phosphatase and the noncollagenous protein osteocalcin. Alkaline phosphatase is an enzyme on the osteoblasts' surface whose function is uncertain, but it is suspected to play a role in mineralization and in pumping calcium across cellular membranes. Osteocalcin is a protein of uncertain function secreted by osteoblasts and found in bone matrix. Blood concentrations of osteocalcin and the bone isoenzyme of alkaline phosphatase correlate well with osteoblast synthetic activity.

Osteocytes are osteoblasts that have been surrounded by mineralized bone matrix ([Fig. 16-5](#)). They occupy small spaces in the bone called lacunae (singular: lacuna) and make contact with osteoblasts and other osteocytes by means of long cytoplasmic processes that pass through thin tunnels in the bone called canaliculi (singular: canaliculus). Under conditions of extreme stress to calcium homeostasis, osteocytes might have the ability to resorb perilacunar mineral and matrix, thus enlarging the lacuna (osteocytic osteolysis). This process apparently is rare and likely does not contribute significantly to development of osseous lesions. Osteocytes also retain a limited capacity to form bone. Other functions of osteocytes are somewhat speculative and are presented later in osteoblast-osteocyte interactions.

### Box 16-1 Bone Cell Function

Osteoblasts	Cells on the surface of bone that form bone matrix, initiate bone mineralization, and initiate bone resorption in response to physiologic stimuli
Osteocytes	Cells residing within bone matrix that detect changes in stress (force applied to the bone) and strain (structural deformation in response to the force) in the bone and signal these changes to osteoblasts to either form bone or initiate resorption
Osteoclasts	Cells that resorb bone

**Fig. 16-1 Osteoblasts and osteocytes, long bone, young dog.** Prominent cuboidal osteoblasts (*arrows*) line the endosteal surface. Hematopoietic marrow is present. More mature (older) osteocytes are present deeper in the cortex and are recognizable as small elliptical cells. The more recently embedded (younger) osteocytes are closer to the surface, ovoid, and in large lacunae. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-2 Osteoblasts, bone, tibia, rodent.** Osteoblasts with abundant endoplasmic reticulum (ER) on an actively mineralizing surface. Cell processes (arrows) of the osteoblasts extend out into the osteoid. Mineralization (black spicules) is initiated within matrix vesicles (arrowheads), then grows onto the adjacent collagen. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-3 Osteoblasts, vertebra, adult dog.** Osteoblasts on the endosteal surface are fusiform with little cytoplasm and form an inconspicuous layer between the cortical bone and active hematopoietic marrow of the adult axial skeleton. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-4 Inactive osteoblast, bone, tibia, rodent.** Inactive osteoblast with reduced cytoplasmic volume because of the less-developed or less-active organelles, which are necessary for collagen synthesis. The narrow rim of unmineralized (*white*) bone matrix, the lamina limitans, acts as a protective layer for the underlying mineralized bone. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Osteoclasts are multinucleated cells responsible for bone resorption (Fig. 16-6). They are derived from hematopoietic stem cells of the granulocyte-monocyte series. They have abundant eosinophilic cytoplasm and a specialized brush border adjacent to the bone surface that is being resorbed (Fig. 16-7). For osteoclasts to resorb bone, they must gain access to the bone surface that is usually covered by osteoblasts, and they must attach to the mineralized surface by transmembrane receptors in their sealing zones. These receptors bind to specific ligands in the matrix, likely residing in noncollagenous proteins. Osteoclasts are not able to bind to unmineralized bone matrix even though it contains these same ligands. Once bound to the matrix, the osteoclast resorbs bone in two stages. First, the mineral is dissolved by secretion of hydrogen ions through a proton pump located in the brush border. These hydrogen ions are derived from carbonic acid produced within the osteoclast from water and carbon dioxide by the enzyme carbonic anhydrase. Second, the collagen of the matrix is cleaved into polypeptide fragments by cysteine and metalloproteinases and cathepsins released from the numerous lysosomes in the osteoclast and secreted through the brush border. The concavity in the bone created by the resorption is called a Howship's lacuna. Physiologically, osteoclast activation is controlled by osteoblasts and bone marrow stromal cells (see later discussion of interactions). Calcitonin is a systemic inhibitor of osteoclasts. Osteoclasts have receptors for calcitonin and respond to this hormone by involuting their brush border and detaching from the bone surface. The activity of osteoclasts can be indirectly measured by determining blood concentrations of collagen degradation products (pyridinoline and deoxypyridinoline cross links).

1043

**Fig. 16-5 Osteocyte, bone, tibia, rodent.** A recently embedded osteocyte still has residual rough endoplasmic reticulum and Golgi apparatus used during its osteoblastic period. Cell processes are extending into the mineralized matrix (*black*) through tunnels called “canaliculi” (*arrows*). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Osteoblast-osteocyte interactions are apparent from their connections to each other by thin, tortuous, cytoplasmic processes. This network of osteoblasts and osteocytes forms a functional membrane that separates the extracellular fluid bathing bone surfaces from the general extracellular fluid and can regulate the flow of calcium and phosphate ions to and from the bone fluid compartment (Fig. 16-8). Because of the large surface area of perilacunar and canalicular bone available for rapid ion exchange, significant amounts of calcium can be shifted from the bone fluid compartment to the extracellular fluid compartment without structural changes within the bone. In addition, this network allows osteocytes to detect alternations in the fluid flow within the bone extracellular fluid compartment. It is thought such flow contributes to electric currents called streaming potentials. Changes in these streaming potentials caused by altered stress and strain on the bone or disruption of these potentials by microcracks (minuscule fractures within the bone visible only microscopically) might be detected by osteocytes with subsequent signaling to the overlying osteoblasts to initiate bone formation or resorption.

1043

1044

**Fig. 16-6 Osteoclasts, long bone, young dog.** Several multinucleated cells (osteoclasts) (*arrows*) are resorbing endocortical bone and creating a scalloped appearance of the surface. These scalloped cavities of resorbed bone are called Howship's lacunae. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-7 Osteoclasts, brush border, bone, tibia, rodent.** Spicules of hydroxyapatite (*arrows*) are apparent between the projections of the brush border (*BB*). The crystals have been separated from the matrix and are in the process of being dissolved by acid and enzyme secretions across the brush border. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Fig. 16-8 Schematic diagram of the hypothesized intracellular and extracellular movement of calcium (*arrows*) in bone and the relationships of osteoblasts, osteocytes, and osteoclasts to blood vessels, extracellular fluid (ECF), and bone tissue fluid (BTF) compartment. (Redrawn from Matthews JL, Vander Wiel C, Talmage RV: Adv Exp Med Biol 103:456, 1978.)

Osteoclast-osteoblast/stromal cell interactions are required for physiologic resorption of bone. The bone surface is protected from osteoclastic resorption by a continuous layer of osteoblasts and also by a very thin layer of unmineralized bone matrix normally present beneath resting osteoblasts (lamina limitans) (Fig. 16-4). Osteoclasts are not able to bind to unmineralized bone matrix). For parathyroid hormone (PTH) to initiate bone resorption, receptors on the osteoblast bind PTH (osteoclasts do not usually express receptors for PTH). The binding of PTH to osteoblasts signals them to retract and secrete collagenases, which erode the unmineralized layer of matrix allowing osteoclasts access to a mineralized bone surface. In addition, osteoblasts and stromal cells activated by binding PTH, and in response to a variety of other bone resorbing stimuli (1, 25 dihydroxyvitamin D<sub>3</sub>, interleukin [IL]-1 and IL-11, tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ], prostaglandin E<sub>2</sub> [PGE<sub>2</sub>], and glucocorticoids) will express or secrete osteoclast differentiation factor (ODF), also called rank ligand. ODF binds to receptors on osteoclasts (rank) and activates the resorption process. Osteoblasts and bone marrow stromal cells also can secrete osteoprotegerin (OPG), a protein that blocks ODF. OPG expression can be stimulated by transforming growth factor- $\beta$  (TGF- $\beta$ ). Therefore osteoblasts and stromal cells have the ability to both up- and down-regulate osteoclastic bone resorption (Fig. 16-9). In conditions of inflammation and necrosis, inflammatory mediators such as IL-1 and TNF- $\alpha$  can stimulate osteoclasts directly, causing bone resorption independent of viable osteoblasts.

## Pathologic Basis of Veterinary Disease, 4th Edition

16.1.1.2

### BONE AT THE ORGANIC MATRIX AND MINERAL LEVEL

The mineralized matrix of bone, its interstitium, provides the organ's strength. Bone organic matrix consists of type I collagen and “ground substance” (the noncollagenous extracellular matrix: water, proteoglycans, glycosaminoglycans, noncollagenous proteins, and lipids, discussed later). Type I collagen polymers are secreted by osteoblasts and assembled into fibrils that are embedded in the ground substance and then mineralized. The type I collagen molecule is composed of three intertwined amino acid chains. Unique to these chains is the hydroxylated form of the amino acid proline (hydroxyproline). Type I collagen molecules have extensive cross linkages among the amino acid chains within the molecule and between adjacent molecules. Collagen molecules are deposited in rows with a gap between each molecule and with the rows staggered so that the molecules overlap by one fourth of their length. This specific packing of the collagen molecules and the cross linkages contribute to the strength and insolubility of the fibrous component of the bone matrix. Other than in rapidly deposited bone (woven bone found in primary trabeculae, bone of early fetal development, and pathologic conditions such as fracture repair), collagen fibers are arranged in parallel lamellae (singular: lamella) and called lamellar bone. The orientation of the collagen fibers in each lamella is slightly different, giving a herringbone-like pattern. In Haversian (osteonal) bone, lamellae are arranged concentrically (Fig. 16-10). In trabecular bone, the lamellae usually are arranged parallel with the surface. The collagen content of bone and its lamellar arrangement give bone its strength and flexibility. The ground substance of bone, also synthesized by osteoblasts, consists of noncollagenous proteins, proteoglycans, and lipids. Many of the noncollagenous proteins are cytokines capable of influencing bone cell activity. These cytokines, such as TGF- $\beta$ , may play pivotal roles in controlling the extent of bone formation and resorption in normal remodeling and in disease (Fig. 16-11). Also, among the noncollagenous proteins are enzymes that can function in degradation of collagen (e.g., matrix metalloproteinases) and can destroy inhibitors of mineralization (e.g., pyrophosphatases). Other noncollagenous proteins in the matrix can function as adhesion molecules and help bind cells to cells, cells to matrix, and mineral to matrix. Examples are osteonectin and osteocalcin. The role of proteoglycans in bone matrix is uncertain. They could play a role in inhibiting mineralization and promoting cell matrix interactions. Lipids can assist in binding calcium to cell membranes and in promoting calcification.

1044

1045

Fig. 16-9 **Schematic diagram showing interaction between stromal cells/osteoblasts and osteoclast/osteoclast precursors.** Stromal cells and osteoblasts produce “rank ligand,” which binds to the “rank” receptor on the osteoclast and its precursors; this binding stimulates osteoclasts. Conversely, osteoblasts and stromal cells can inhibit the activation of osteoclasts by secreting osteoprotegerin, which can bind to “rank ligand” and block its binding to “rank receptor.” *M-CSF*, Macrophage colony-stimulating factor; *NF κB*, nuclear factor kappa B. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

**Fig. 16-10 Osteonic remodeling, bone, endocortical surface.** Endocortical surface of bone has undergone extensive osteonal remodeling. Collagen fibers are birefringent when viewed in appropriate plane with polarized light. Usually, alternate lamellae polarize when viewed in the same plane. This alternating pattern of birefringence demonstrates the parallel arrangement of collagen layers in lamellar bone. All of the bone present is lamellar. Much of the cortex has been remodeled into osteonal bone (concentric layers with central channel for vessels and nerves), but there are areas of cortex that remain unosteonized (unremodeled). Unstained and fully mineralized. Polarized light micrograph. *(Courtesy Dr. L. P. Krook, College of Veterinary Medicine, Cornell University.)*

1045

**Fig. 16-11** Schematic diagram illustrating that osteoclasts are able to liberate and activate growth factors from the matrix that are stimulatory to osteoblast progenitor cells and “couple” the process of osteoclastic bone lysis with subsequent bone formation. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Bone mineral is in the form of a crystal called hydroxyapatite. Fully mineralized bone is approximately 65% of the bone by weight and consists in part of calcium, phosphorus, carbonate, magnesium, sodium, manganese, zinc, copper, and fluoride. The mineral content gives bone its hardness. The production of osteoid (unmineralized organic matrix) by osteoblasts is followed by a period of maturation, after which mineral is deposited at the exchange of water. The process of mineralization is initially rapid until the matrix is about half saturated with mineral. Complete saturation of the matrix with mineral takes several months. Mineralization in woven bone is initiated within cytoplasmic blebs (matrix vesicles) of osteoblasts in the osteoid (Fig. 16-2). Initiation of mineralization involves concentrating calcium, phosphorus, and other elements in these matrix vesicles (intracellularly) to a concentration that causes precipitation of the mineral in the vesicle in the form of amorphous (not yet crystalline) hydroxyapatite. These vesicles have phospholipids and enzymes, such as alkaline phosphatase and adenosine triphosphatase in their membranes. It is speculated that these membrane phospholipids attract calcium and phosphorus to the surface of the vesicle, and that the alkaline phosphatase and adenosine triphosphatase enzymes might function in the pumping of these ions into the cell against a concentration gradient.

Upon reaching a critical mass, the amorphous mineral becomes crystalline. The crystalline hydroxyapatite pierces the lipid membrane of the matrix vesicle and extends to the gaps (holes) between collagen molecules. It is within these holes that the mineral crystals are first deposited in collagen. For the mineralization to spread beyond these gaps between the tropocollagen molecules, it is necessary for naturally occurring inhibitors of mineralization in the matrix to be destroyed. One such inhibitor is inorganic pyrophosphate. Inorganic pyrophosphates are normal by-products of cellular metabolism and are

## Pathologic Basis of Veterinary Disease, 4th Edition

---

deposited in unmineralized matrix by osteoblasts. The phosphatase enzymes described previously on the matrix vesicles have the ability to cleave these inorganic pyrophosphates and in doing so, destroy these inhibitors. Once the gaps are filled with mineral and inhibitors of mineralization are destroyed, the process continues so that eventually the surfaces of collagen fibers as well as spaces between collagen fibers are mineralized. Initiation of mineralization in lamellar bone might not require matrix vesicles. Glycoproteins, such as sialoprotein and osteonectin, can act as the nidus for the mineralization process.

1046

16.1.1.3

### BONE AS A TISSUE

1047

Bone is organized into osteons or Haversian systems in the compact bone of the cortex and in the bone beneath articular surfaces (subchondral bone) of larger animals. In cortical bone, osteons are cylinders of concentric layers of lamellae that contain centrally located vessels and nerves. These cylinders are oriented parallel to the longitudinal axis of the bone. Haversian or compact bone is made up of numerous osteons (Fig. 16-12 and Fig. 16-10). Bone between the osteons is called interstitial lamellae. Layers of bone oriented parallel to the internal and external circumference of the bone (beneath the endosteal and periosteal surfaces) are called circumferential lamellae. The osteonal system provides channels for the vascular supply to thick bone of the cortex and also acts as tightly bound cables, giving the cortical bone strength yet limited flexibility. This osteonal system also might be important in limiting propagation of microcracks in bone by diverting cracks along cement lines, which are collagen poor, and proteoglycan-rich seams between adjacent remodeling or modeling units (see later discussion). In histologic sections, cement lines appear as basophilic lines in H&E stained sections of decalcified bone.

1047

1048

Fig. 16-12 **Schematic diagram of the structure of compact and cancellous bone.** **A**, Longitudinal section of a long bone showing both cancellous and compact bone. **B**, A magnified view of compact bone. **C**, Section of a flat bone. Outer layers of compact bone surround cancellous bone. Fine structure of compact and cancellous bone is shown to the right. (**A**, **B**, and **C**, From Thibodeau GA, Patton KT: Anatomy and physiology, ed 5, St Louis, 2003, Mosby.)

In contrast to the dense compact bone of the cortex and the subchondral bone plates, the bone in the medullary cavity is in the form of anastomosing plates or rods and is called cancellous, trabecular, or spongy bone (Fig. 16-12). The orientation of the trabeculae usually reflects adaptation (modeling) to mechanical stresses applied to the bone. This is readily apparent when examining the patterns of the trabeculae in the femoral neck. They are in lines and arcs perpendicular to the stress applied and thicker and more numerous on the ventral aspect (side of compression) compared with the dorsal aspect (side of tension). The lamellae within a trabecula usually are arranged parallel to the surface of the trabecula. They are not arranged into tubes or osteons, as in cortical bone.

In most species, bone undergoes a low but constant replacement called remodeling: Old bone is resorbed and replaced by new. The basal level of this remodeling activity (number of sites in the skeleton being remodeled at any one time) is likely “programmed” for each species. The number of these active remodeling sites, however, can be markedly increased or decreased in response to altered mechanical use (see later discussion). This turnover of old bone to new bone allows for the repair of accumulated microscopic injury in the bone (microfractures). In normal bone remodeling, slightly less bone is replaced than removed, leaving a small negative net change in bone mass with each remodeling cycle. This partly explains the reduced bone mass in aged animals. In disease states such as hyperparathyroidism, resorption is often increased and formation decreased, leaving a significant net negative bone balance. Not all species undergo bone remodeling; in small, short-lived animals, such as the mouse and rat, cortical bone is not remodeled. Not all areas of bone in larger species undergo remodeling. It is common to find unremodeled cortical bone in aged small dogs and cats. These unremodeled regions likely have been spared vigorous mechanical use (stress) and did not experience strain (deformation in structure) sufficient to initiate remodeling. The remodeling unit of cortical bone is called the osteon, and for trabecular bone, it is called the basic structural unit. The shape of the osteon is cylindrical. The basic structural unit has the contour of a

## Pathologic Basis of Veterinary Disease, 4th Edition

---

shallow trench filled with parallel lamellae. The time required from initiation to completion of these remodeling units is estimated to be 3 to 4 months in human beings. At the periphery of these remodeling units are cement lines, which separate the units from each other. Because there are no collagen fibers extending across the cement lines, there can be slight movement of these columns or plates of bone in relation to each other providing flexibility and possibly a means of distributing shearing forces. Cement lines indicating the limit of previous resorptive activity are usually somewhat scalloped, reflecting the Howship's lacunae created by osteoclasts. These lines are called "reversal lines" (where resorption stopped and the process was reversed by formation) (Fig. 16-13). Cement lines also can occur when osteoblast formation ceases and subsequently resumes. The reason for the cessation is usually not obvious. These cement lines are called "resting lines" and are usually smooth and follow the contour of the overlying surface.

1048

1049

The term "modeling" is used to describe change of the shape or contour of a bone in response to normal growth, altered mechanical use, or disease. In modeling, bone surfaces (periosteal, endosteal, intracortical, and trabecular surfaces) can go from resting directly to either formation or resorption depending on the stimulus. This process allows the shape or size of bone to change and enables the medullary cavity to enlarge and the overall shape of the bone to be maintained while the bone is growing. Modeling is in contrast to normal remodeling in which resorption must precede formation to keep bone mass and shape constant.

16.1.1.4

### BONE AS AN ORGAN

Individual bones of the skeleton vary in their manner of formation, growth, structure, and function. Flat bones of the skull develop by the process of intramembranous ossification, in which mesenchymal cells differentiate into osteoblasts and produce bone directly. Cartilage precursors are not involved. Most bones develop from cartilaginous models by the process of endochondral ossification. Cartilaginous models are invaded by vessels, and primary (diaphyseal) and secondary (epiphyseal) centers of ossification develop and provide for further growth and increasing strength.

**Fig. 16-13 Remodeling in compact subchondral bone adjacent to a joint with bacterial infection, bone, horse.** Resting cement appear as basophilic smooth lines indicating where formation has temporarily stopped (*arrowhead*). Reversal lines are scalloped basophilic lines (*arrow*) indicating where in the bone resorption stopped and was followed by formation. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

The long appendicular bones and the vertebral bodies are divided anatomically into epiphyses, metaphyseal growth plates (physes), metaphyses, and diaphyses (Fig. 16-14).

### 16.1.1.5 BLOOD SUPPLY TO BONE

Arterial blood from the systemic circulation enters bones through nutrient, metaphyseal, periosteal, and epiphyseal arteries (Fig. 16-15). Nutrient arteries penetrate the diaphyseal cortex through a nutrient foramen covered by strong, protective fascial attachments; once within the medulla, these arteries divide into proximal and distal intramedullary branches. Other arteries penetrating the cortex are the proximal and distal metaphyseal arteries. These are smaller and more numerous than the nutrient artery. They penetrate the cortex and anastomose with the terminal branches of the nutrient arteries in the medullary cavity. These anastomoses protect against infarction if a nutrient artery is obstructed.

1049

1050

Fig. 16-14 **Schematic diagram of a longitudinal section of long bone (tibia) showing spongy (cancellous) and compact bone.** The name *epiphyseal plate* in the diagram is commonly used but not preferred for this growth plate. This growth plate elongates the metaphysis and is the metaphyseal growth plate or physis. The growth plate responsible for enlarging the epiphysis is the articular-epiphyseal complex (see Bone Growth). (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 5, St Louis, 2003, Mosby.)

**Fig. 16-15 Correlation of long bone development and vascularization.**

The primitive mesenchyme that makes up the skeletal primordia has no blood vessels (**A**). This mesenchyme condenses and undergoes mineralization, and a bony collar forms in the periosteum of the diaphysis (**B** and **C**). The nutrient artery enters the mineralized cartilaginous tissue in the diaphysis, bringing osteogenic and osteoclast precursors enabling endochondral ossification to occur (primary center of ossification) (**D**). Similarly, the epiphyseal arteries bring these cells to the secondary centers of ossification in the epiphyses (**E**). Extensive anastomoses develop as the bone continues to develop and as the growth plates close (**F** and **G**). (From Banks WJ: Applied veterinary histology, ed 3, St Louis, 1993, Mosby.)

Small periosteal arteries also pass through the diaphyseal cortex at sites of fascial attachment and can supply one quarter to one third of the outer cortex. The remainder of the cortex is supplied by the nutrient artery and its anastomotic branches. This blood flow is centrifugal (from medulla to periosteum) because of greater pressures in the intramedullary vessels. The chondrocytes of the physis nearest the epiphysis are supplied by epiphyseal arteries. The chondrocytes of the physis nearest the metaphysis are supplied by branches of metaphyseal and nutrient arteries. As capillaries from these vessels approach the metaphyseal side of the physis, they make abrupt turns (loops). These loops are sites predisposed to bacterial embolization in neonatal sepsis.

16.1.1.6

### BONE GROWTH

Bone grows in length by interstitial growth within the cartilage growth plates (Fig. 16-16). The mineralized longitudinal septa of the growth plates serve as struts on which bone is deposited. This process is called endochondral ossification. The metaphyseal growth plate, or physis, is primarily responsible for lengthening the bone. Cartilage of the metaphyseal growth plate is divided into a reserve or resting zone, a proliferative zone, and a hypertrophic zone (Fig. 16-17). The hypertrophic zone is sometimes further subdivided into zones of maturation, degeneration, and calcification. The zone of degeneration is suspected to be a form of apoptosis, but usually there is nuclear and cytoplasmic swelling light microscopically, and this is not typical of apoptosis. The resting or reserve zone serves as a source of cells for the proliferating zone where cells multiply, accumulate glycogen, produce matrix, and become arranged in longitudinal columns. In the hypertrophic zone, chondrocytes secrete macromolecules that modify the matrix to allow capillary invasion and initiate matrix mineralization; eventually these chondrocytes die. The overall lengthening of the bone is due to a combination of the effects of the proliferating zone and hypertrophying zone. Calcification begins in the longitudinal septa of cartilaginous matrix between columns of chondrocytes. Matrix vesicles derived from chondrocytes (analogous to those described previously for mineralization of bone) form in the hypertrophic zone and initiate the mineralization process as previously described for bone. The processes of mineralization and vascular invasion of the growth plate are co-dependent events. To supply salts for the mineralization, a nearby blood supply is necessary, and vascular invasion does not take place in mammalian growth plates unless there is mineralization of the longitudinal septum. Vascular invasion of the growth plate is a critical step in endochondral ossification. Blood vessels from the metaphysis invade into the advancing growth plate, bringing with them osteoblasts that form bone on the cartilage spicules (Fig. 16-17). The chondroosseous junction in the metaphysis is a fragile lattice of bone-covered spicules of calcified cartilage (primary trabeculae). As the growth plate advances and elongates the metaphysis, the more mature trabeculae deeper in the metaphysis become fewer and thicker (secondary and tertiary trabeculae) and often contain residual fragments of cartilage.

1050

1051

Fig. 16-16 **Growth plate, long bone, dog.** Resting (*R*), proliferating (*P*), and hypertrophic (*H*) zones of the growth plate are visible. Apoptotic chondrocytes are released from their lacunae by invading vessels and chondroclasts leaving only the longitudinal septa (*arrow*) as a base on which bone will be deposited to form a primary trabeculae. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-17 Schematic diagram of the major blood supply to the physis.** Branches of the epiphyseal artery supply the resting zones of the growth plate. Branches of the metaphyseal artery form capillary loops at the metaphyseal end of the physis undergoing endochondral ossification. (From Banks WJ: Applied veterinary histology, ed 3, St Louis, 1993, Mosby.)

Growth of the epiphysis also contributes to the overall length of the bone and is accomplished by endochondral ossification at the articular-epiphyseal (AE) complex. The AE complex is the zone of endochondral ossification beneath the articular cartilage in growing animals (Fig. 16-18). The residue of the AE complex will become the zone of mineralized articular cartilage in the adult.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Growth plates are thickest when growth is most rapid; as growth slows, the plate becomes thin and “closes” (it is entirely replaced by bone) at skeletal maturity (Fig. 16-19). The times for closures of specific growth plates in an individual animal can vary greatly. The AE complex usually closes before the physis. The physes of vertebra will usually remain open longer than the physes of the long bones. Androgens and estrogens play a major role in determining the time of growth plate closure, and early castration in the dog results in delayed growth plate closure with the subsequent increased length of bones.

Bone grows in width by intramembranous bone formation. Except for articular surfaces (including the ends of the vertebral bodies), the surfaces of bones are covered by periosteum. This covering is a thin membrane that is loosely attached to underlying bone except at heavy fascial attachments on bony prominences and at tendon insertions, where its attachments are strong and are associated with large vessels penetrating the underlying bone. Microscopically the periosteum is composed of an outer fibrous layer that provides structural support and an inner osteogenic or cambium layer, capable of forming normal lamellar appositional bone on the cortex of growing bones, and abnormal woven bone formation in response to injury (Fig. 16-20). The periosteum is well supplied with lymph vessels and with fine myelinated and nonmyelinated nerve fibers that explain the intense pain when the periosteum is injured.

1051

1052

**Fig. 16-18 Articular-epiphyseal complex (AEC), bone, articular cartilage, young dog.** The AE complex is the growth plate beneath the articular cartilage. Its function and structure are essentially the same as the metaphyseal growth plate (Fig. 16-16). H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-19 Bone and cartilage, humerus, proximal end, adult dog.**

Growth of the skeleton, specifically the epiphysis, has ceased, and cartilage that was portion of the articular epiphyseal complex is retained as the mineralized layer of the articular cartilage (MAC). The MAC is separated from the unmineralized articular cartilage by a basophilic line called the tidemark (*arrow*). Collagen fibers cross the tidemark and are shared by the MAC and overlying unmineralized articular cartilage. There are no collagen fibers crossing the junction between the subchondral bone and MAC because they are of different collagen types. H&E stain. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

The periosteum covering the physis is called the perichondrial ring. The perichondrial ring adds new cartilage to the periphery of the physis, enabling the physis to expand in width as the animal grows. The metaphyseal cortex immediately adjacent to the perichondrial ring is normally very thin in the growing bone because its surfaces are the sites of very active osteoclastic bone resorption. Structurally, this area is the weakest part of the bone.

**Fig. 16-20 Periosteum, bone, dog.** The outer fibrous layer (F) and inner osteogenic layer (O) line the periosteal surface. The osteogenic layer is able to rapidly deposit woven bone as a nonspecific response to injury. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

### 16.1.2 NORMAL STRUCTURE AND FUNCTION OF JOINTS

Joints (articulations) join skeletal structures, provide for movement, and in some cases have shock-absorbing functions. Most of the material in this section is confined to the synovial joints.

Synovial joints occur in both the axial and appendicular skeleton. Such joints allow for a variable degree of movement and, anatomically, are composed of two bone ends joined together by a fibrous capsule and ligaments. The inner surface of the articular capsule is lined by a synovial membrane, and the bone ends are covered by articular cartilage. The joint space contains synovial fluid, and fibrocartilaginous menisci or disks are present at some sites (e.g., femoro-tibial and temporomandibular joints). Synovial joints operate with very low coefficients of friction and are self-lubricating. Articular cartilage serves as the bearing substance and subchondral bone as the supporting material. Articular cartilage functions to minimize friction created by movement to transmit mechanical forces to underlying bone and to maximize the contact area of the joint under load. Joints receive and absorb energy of impact. Both articular cartilage and subchondral bone deform under pressure, but it is the subchondral bone that has the most significant force-attenuating properties.

#### 16.1.2.1 ARTICULAR CARTILAGE

Articular (hyaline) cartilage is normally a white to blue-white material with a smooth, moist surface. Cartilage thickness is greatest in the young and at sites of maximal weight bearing. Thinning and yellow discoloration occur in old age. At its margins, articular cartilage merges with a periosteal surface that is lined by fibrous tissue contiguous with the synovial membrane. Synovial fossae are normal depressions on non-weight-bearing articular cartilage surfaces (Fig. 16-21, A and B) that develop bilaterally in the larger

1052

1053

## Pathologic Basis of Veterinary Disease, 4th Edition

---

appendicular joints of the horse, pig, and ruminant. These are not present at birth but are fully formed by skeletal maturity. The function of synovial fossae is not known. They are significant because they can easily be mistaken for lesions. Articular cartilage contains no nerves or blood or lymph vessels, and its nutrients are obtained by diffusion from synovial fluid and to a lesser extent from subchondral vessels. In the immature skeleton, articular cartilage overlies the still growing cartilage of the epiphysis (epiphyseal cartilage). The epiphyseal cartilage contains blood vessels and will undergo endochondral ossification and thereby contribute to the growth of the epiphysis. Defects at the junction of the articular cartilage and epiphyseal cartilage (the articular epiphyseal complex) occur in osteochondrosis. At skeletal maturity, the epiphyseal cartilage has been replaced by a bony subchondral plate. The deeper regions of the articular cartilage mineralize and remain—they are not removed by endochondral ossification. The junction between the unmineralized articular cartilage and the deeper mineralized cartilage is called the tidemark (Fig. 16-19). As animals age, multiple tidemarks can be formed, indicating an advance (thickening) of the mineralized layer of articular cartilage and thinning of the overlying nonmineralized articular cartilage. The mineralized cartilage serves to anchor articular cartilage to subchondral bone and limits the diffusion of substances between bone and cartilage.

Articular cartilage is 70% to 80% water by weight. It is a viscoelastic, hydrated fiber-reinforced gel that contains chondrocytes, collagen fibers (mostly type II), and proteoglycan aggregates. The largest proteoglycan is aggrecan. Aggrecan is composed of the immensely long, nonpolysulfated glycosaminoglycan hyaluronan, to which core proteins are attached in a perpendicular arrangement like bristles on a brush. Again, in bottle brushlike fashion, smaller polysulfated glycosaminoglycans (chondroitin sulfate and keratan sulfate) are attached to these core proteins. Aggrecan is extremely hygroscopic. By binding water and forming a hydrated gel, proteoglycans provide stiffness to resist compression and impede the outflow of water when cartilage is under load (weight bearing). The lacunae in which chondrocytes reside are different from those in bone. There is no fluid space within a chondrocyte lacuna as in osteocyte lacunae. The space in the chondrocyte lacunae often seen in light microscopy is a shrinkage artifact. In fact, chondrocytes have surface receptors for matrix components (e.g., hyaluronan), so there is direct communication between matrix and cell.

**Fig. 16-21 Synovial fossa, joint, radius and ulna, bone, proximal end, adult horse. A,** Synovial fossae are recognized as depressions in the cartilage on the non-weight-bearing surfaces of the sagittal ridge of the radius and in the semilunar notch of the ulna (*arrows*). The parallel linear grooves apparent on the weight-bearing surface (articular cartilage) of the radius are the result of degenerative joint disease. **B,** Histologically, synovial fossae are regions where the endochondral ossification of the epiphyseal cartilage is complete (leaving no articular cartilage), and only a thin fibrous membrane is present on the surface separating the bone from the joint cavity. H&E stain. (*A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

Collagen fibers provide tensile strength and are arranged in arcades so that the tops of the arcades are parallel to the articular surface, and the sides are perpendicular to the surface and parallel with the radial or intermediate zone of chondrocytes. Functionally the superficial zone of articular cartilage (which has significant amounts of type I collagen) resists shearing forces, the middle zone functions in shock absorption, and the mineralized deep zone of cartilage serves to attach articular cartilage to the subchondral bone by their irregular (and therefore interlocking) interfaces. In scanning electron micrographs, the surface of articular cartilage is not smooth but rather has numerous depressions that can serve as reservoirs for synovial fluid.

Chondrocytes are responsible for the production, maintenance, and turnover of intercellular substances. 1053  
Normal turnover is enzymatic and is balanced by enzyme inhibitors. Disease occurs if there is increased 1054  
destruction or decreased synthesis of components of the matrix. It is important to remember that compared with bone, which normally renews itself by remodeling, only the proteoglycans turn over in cartilage. The cells and collagen of cartilage are infrequently, if ever, replaced under normal conditions. Chondrocytic mitotic activity is minimal in adult animals, and cellularity of articular cartilage declines with age.

### 16.1.2.2 ARTICULAR CAPSULE/SYNOVIUM/SYNOVIAL FLUID

The articular capsule consists of outer fibrous and inner synovial tissue layers. The outer layer is a heavy sheath that contributes to joint stability and at its insertion attaches to bone at the margins of the joint and thereby encloses a segment of bone of variable length within the joint cavity. It is well supplied with blood

## Pathologic Basis of Veterinary Disease, 4th Edition

---

vessels and nerve endings. The synovial membrane covers all the inner surfaces of the joints except for that of the surface of the articular cartilage. The synovial membrane is normally very thin and barely visible grossly. Tiny surface projections (villi) are normally present and are more prominent in some areas than in others. Synovial intimal or lining cells, one to four cells thick, form a discontinuous surface layer (Fig. 16-22). They are designated as A cells (phagocytic cells that produce hyaluronate); B lymphocytes (fibroblast-like cells, rich in rough endoplasmic reticulum), which may produce glycoprotein; and “intermediate” cells, which have some of the characteristics of both. A cells are of bone marrow origin and are part of the monocyte-macrophage cell system. The synovial subintima can be classified according to the type of predominant tissue (areolar, adipose, or fibrous). It contains blood and lymph vessels that supply and drain the intraarticular structures. Adipose tissue sometimes accumulates in the deep layers of the synovium, forming fat pads that serve as soft cushions in joint cavities (e.g., the infrapatellar fat body of the stifle joint separates the fibrous layer of the articular capsule from the synovium on the anterior aspect of the joint distal to the patella).

**Fig. 16-22 Synovial membrane, joint, dog.** The normal synovial membrane consists of an incomplete layer of histiocytes (phagocytic cells) and fibrocytes with subjacent loose fibrous and/or fibrofatty tissue. The joint lumen is at the top. H&E stain. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

Synovial fluid is a dialysate of plasma, supplemented with proteoglycans from the synovial intima that nourishes and lubricates intraarticular structures. Normally, it is a clear, colorless to pale yellow, viscous fluid.

Joint lubrication depends on the microscopic roughness, elasticity, and hydration of articular cartilage and on the presence of mucin (hyaluronate and glycoprotein) in synovial fluid. Lubrication of the synovial membrane itself is hyaluronate-mediated boundary lubrication. Boundary lubrication implies that a substance sticks to the surface and minimizes contact. Lubrication of articular cartilage is accomplished by the complementary action of weeping (squeeze-film) and boundary lubrication. In weeping lubrication, the weight-bearing articular surface is supplied with pressurized fluid that carries most of the load. This fluid is synovial fluid admixed with water released from the underlying cartilage subsequent to pressure of weight bearing. When non-weight-bearing, the water returns to the cartilage because of the hydrophilic properties

## Pathologic Basis of Veterinary Disease, 4th Edition

of proteoglycans. This flushing of water in and out of the articular cartilage enables nutrients to enter cartilage from the synovial fluid and waste products to be removed. Joint stiffness is often due to inability of periarticular soft tissue to lengthen rather than to intraarticular friction.

### 16.1.2.3 SUBCHONDRAL BONE

The subchondral bone acts to support the overlying cartilage and dissipate concussive forces to the peripheral cortical bone (Fig. 16-23). The thickness of the subchondral bone plate varies in proportion to the degree of weight bearing. In larger animals, subchondral bone can be compact osteonal bone.

### 16.1.3 REACTIONS OF BONE TO INJURY

Mechanical forces that can affect bone are both internal and external. Internal forces associated with extremes in work or exercise can influence modeling or remodeling (see previous discussion) and occasionally cause fracture (failure of the bone). External forces (trauma) are more commonly associated with damage to the periosteal surface or fracture of the cortex and/or trabecular bone.

Hormonal agents, particularly calcitriol and parathyroid hormone, enter the bone by the blood stream as described previously.

Infectious agents will be discussed later under Inflammation of Bone.

1054

1055

**Fig. 16-23 Rat.** Compact bone (B) supports the articular cartilage in the adult animal when there is no longer endochondral ossification occurring at the articular epiphyseal complex. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Defense against mechanical forces include the structure of the bone and the bone's ability to model and remodel to adapt to chronic changes in forces applied to it. The dense bone of the cortex enables the bone to

## Pathologic Basis of Veterinary Disease, 4th Edition

---

resist most external forces. The formation of osteons and cement lines in the cortex (primary remodeling) facilitates dissipation of microcracks and bending of the bone in response to stress.

Defense against hormonal agents that are capable of resorbing bone include the protective covering on mineralized surfaces by the lamina limitans and osteoblasts. In addition, hormonal signaling to resorb bone is done through the osteoblast, which has the ability to modulate the resorption signal. Defense against infectious agents will be discussed later under Inflammation of Bone.

The hard tissue of bone can be likened to the rings in a tree in leaving clues to its history embedded in its hard structure. Interpreting these clues requires understanding the ways in which bone uniquely responds to injury (Box 16-2).

### 16.1.3.1 Box 16-2 Bone-Specific Reactions to Injury

1. Disruption of endochondral ossification will affect metaphyseal trabeculae.
2. Bone will change its shape to adapt to damage and abnormal use.
3. Bone will alter its mass in response to systemic disease and altered use.
4. Bone deposited rapidly is woven rather than lamellar.
5. Injured periosteum often responds by forming bone.

Disruption of endochondral ossification can alter the appearance of the primary trabeculae. Examples of this are growth retardation lattice and growth arrest lines. Growth arrest lines can be seen in cases of multiple nutrient deficiencies, such as occur in debilitating disease or general malnutrition. The growth plate becomes narrow (growth is impaired), and the metaphyseal face of the plate can be sealed by a layer of bone as a result of transverse trabeculation (trabecular bone forming parallel with the growth plate). If growth resumes, this layer of bone is left in the metaphysis as the physis moves away from the metaphysis (Fig. 16-24, A and B). The bony lines parallel to the growth plate that can be seen grossly and radiographically in such conditions are called growth arrest lines.

A growth retardation lattice results from acquired impairment of osteoclastic activity within the primary trabeculae, which causes retention of primary trabeculae. These trabeculae elongate because of continued production by the growth plate. The retention of the primary trabeculae results in a dense band of vertically oriented trabecular bone beneath the growth plate; this band is called a growth retardation lattice (Fig. 16-25, A and B). The band is apparent because the normal modeling process that resorbs many primary trabeculae completely and molds the remaining ones into progressively fewer but thicker secondary and tertiary trabeculae is impaired. Diseases that cause growth retardation lattices include canine distemper and bovine viral diarrhea. In addition, toxic damage to osteoclasts, such as in lead poisoning, can cause a growth retardation lattice (lead line). The name *growth retardation lattice* is perpetuated here because it is in common use, but it is important to understand that the lesion is in modeling of the trabeculae rather than a reduction in longitudinal growth. Abnormal retention of primary trabeculae also can be seen with congenital defects in the function of osteoclasts (see later discussion of osteopetrosis).

1055

1056

Fig. 16-24 **Growth arrest lines, long bone, metaphysis, young zebra.** Gross (A) and microscopic (B) appearance of growth arrest lines. The zebra was ill from a bacterial renal infection and became anorexic. The animal made a brief clinical recovery before euthanasia. The period of inappetence is responsible for the parallel horizontal lines of bone in the metaphysis (*growth arrest lines; arrows*). These lines are due to transverse (horizontal) orientation of the trabeculae during the period of slowed growth. H&E stain. (A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Weakening or destruction of the matrix of the physal cartilage, as occurs in animals with hypervitaminosis A and with manganese deficiency, can lead to premature closure of growth plates. If the entire plate is affected, no further longitudinal growth is possible. If closure is focal, as can be seen subsequent with localized

## Pathologic Basis of Veterinary Disease, 4th Edition

inflammation or traumatic damage to vessels, there will be uneven growth of the growth plate, which will produce angular deformities.

**Fig. 16-25 Growth retardation lattice, bone, radius, distal end, dog.**  
Radiograph (A) and longitudinal section (B) of a growth retardation lattice. The increased bone density (D) of the metaphysis represents failure of osteoclasts to resorb unnecessary primary trabeculae. In this case, the failure of osteoclastic resorption was due to canine distemper virus infection of osteoclasts. (A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Osteochondrosis is an important example of diseases caused by disruption of endochondral ossification and will be discussed under disorders of endochondral ossification later.

The ability of bone to change its shape and size (modeling) to accommodate altered mechanical use is called Wolff's Law (Fig. 16-26). Tension and compression are important mechanical factors that affect bone modeling with formation favored at sites of compression and resorption favored at sites of tension. In addition, trabecular bone will align along lines of stress. How bone cells detect altered mechanical use is not precisely known but likely is because of inputs from a variety of signals, including stretch receptors on bone cells, streaming potentials, and piezoelectrical activity. Streaming potentials are electrical currents in bone caused by fluid fluxes through canalicular spaces. These are detected by the osteocytes-osteoblast network. Piezoelectrical activity refers to currents in bone as a result of deformation of collagen fibers and mineral crystals. Electrical currents can affect cell function (bone formation and resorption) and thus influence bone modeling.

Bone mass can be altered to accommodate mechanical use. This is done by the effects of mechanical use on remodeling. Mechanical use is required for maintenance of bone mass. Normal mechanical use suppresses programmed bone resorptive activity. Decreased mechanical use reduces this inhibition (allowing resorption to

1056

proceed) as well as suppresses bone formation. The net effect of decreased mechanical use therefore is less bone because of increased resorption and decreased formation (Fig. 16-27). Increased mechanical use will suppress bone resorption and allow bone mass to increase (Fig. 16-28). Chronic suppression of remodeling, however, could lead to accumulated microcracks, which in turn could override the suppression and stimulate remodeling in regions of the microcracks.

**Fig. 16-26 Hip dysplasia, bone, femoral head and neck, dog.** The shapes of the femoral head and neck are noticeably abnormal. The head is flattened, and periosteal new bone and coalescing osteophytes have formed a massively thickened femoral neck. Macerated and bleached specimen. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-27 Bone, third phalanx, left rear leg, foal.** The leg was in a cast for 2 months to repair an avulsion of gluteal muscles from their insertions and thus could not be used. **A**, Normal right third phalanx. **B**, Left third phalanx. There is pronounced disuse osteopenia (atrophy) compared with the phalanx on the left (**A**). The increase in resorption and decrease in formation associated with disuse has resulted in marked porosity of the cortical and subchondral bone. The cortex now has the appearance of cancellous bone (cancellization of the cortex). (**A and B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Woven bone is the haphazard, hypercellular bone that is deposited in times of repair. Rather than collagen fibers being lamellar, they are irregularly arranged (Fig. 16-29). In woven bone, osteocytes are larger and more numerous per unit area than in lamellar bone, and there is no orientation to their lacunae as seen in lamellar bone in which the alignment of the elliptical lacunae are parallel with the lamellae. When woven bone is formed, the body is responding to a sudden need for more mass and can wait to model and remodel this new bone into lamellar bone once the injury subsides.

The periosteum is programmed to respond to injury by producing woven bone (Fig. 16-29). Usually this is in the form of spicular bone oriented perpendicularly to the long axis of the cortex. If the lesions are nodular, they are called osteophytes. The term enthesiophytes refers to osteophytes in regions of insertions of tendons or ligaments. This reactive periosteal woven bone can be admixed with hyaline cartilage. Lesions even can be predominantly cartilage. The extent to which there is cartilage production by the periosteum is thought to be a result of the oxygen available. When oxygen tension is low, cartilage proliferation can predominate. When oxygen is normal, there may be no cartilage present. Cartilage produced in such circumstances can eventually undergo endochondral ossification. Woven bone produced by the periosteum can undergo modeling to lamellar bone or could undergo osteoclastic resorption and be removed. The periosteum certainly is not limited to production of woven bone. Lamellar bone is produced by the periosteum during slower stages of appositional growth of the diaphysis. In addition to bone formation, the periosteal surface can have osteoclastic bone resorption. During growth, the regions of the cut-back zone of the metaphysis, in which the bone is tapered from its diameter at the physis to the narrower diameter of the diaphysis, have marked osteoclastic bone resorption at the periosteal bone surface. Also, infectious inflammation of the periosteum can lead to marked osteoclastic bone resorption at the periosteal bone surface.

1057

1058

Fig. 16-28 **Osteosclerosis, bone, vertebrae, dog.** Osteosclerosis (increased bone per unit of area) is evident in the four vertebrae in the center of the vertebral column. The cancellous bone of the medullary cavities has been obliterated by newly formed compact bone. The osteosclerosis is in response to increased mechanical stress in the bodies of the vertebrae as a result of degeneration and loss of the intervertebral disks between these vertebrae. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Fig. 16-29 **Cancellous and woven bone.** A spicule of cancellous bone (L) with a sharply demarcated focus of woven bone (W). The woven bone polarizes light, but its collagen fibers are not arranged in uniform parallel layers as in the adjacent normal lamellar bone. This focus of woven bone may represent the site of a healing fracture in this trabecula. Unstained and fully mineralized. Polarized light micrograph. (From Burkitt HG, Young B, Heath JW: Wheater's functional histology: a text and color atlas, ed 3, New York, 1993, Churchill Livingstone.)

### 16.1.4 REACTION OF JOINTS TO INJURY

#### 16.1.4.1 ARTICULAR CARTILAGE

Although articular cartilage contains metabolically active cells, it has a limited response to injury and minimal capacity for repair. Superficial cartilage defects (cartilage erosion) that do not penetrate into subchondral bone persist for long periods. Clusters or clones of chondrocytes (evidence of local chondrocyte replication in response to injury) are present but are ineffective in filling a defect. Some flow or spreading of cartilaginous matrix into the defect might also occur. This phenomenon of matrix flow is likely facilitated by load bearing and joint movement. In short, superficial injuries to articular cartilage neither heal nor necessarily progress, although progression can occur when there is stiffening (sclerosis of) subchondral bone. However, if a cartilaginous defect extends into subchondral bone (cartilage ulceration), the defect is quickly filled with vascular fibrous tissue that often undergoes metaplasia to fibrocartilage, but rarely to hyaline cartilage. Formation of fibrocartilage can be hastened in full-thickness cartilaginous defects by exercise or prolonged passive motion. Injury to articular cartilage is not painful unless the synovium or subchondral bone is involved. Having no blood supply, articular cartilage does not participate directly in the inflammatory response but is very much affected by inflammation in the synovium, subchondral bone, or subarticular growth (vascularized) cartilage of the epiphysis in young animals. Given that alternating compression and release of normal weight bearing facilitates the diffusion of fluid with nutrients into the articular cartilage and fluid with metabolic waste products out of articular cartilage, it follows that constant compression or lack of weight bearing leads to atrophy (thinning) of articular cartilage.

Sterile injury to cartilage can be a consequence of trauma, joint instability, or lubrication failure because of changes in synovial fluid, synovial membrane, or incongruity in joint surfaces. Destruction of articular cartilage in response to sterile injury and infectious inflammation is mediated by a combination of enzymatic digestion of matrix and failure of matrix production when chondrocytes become degenerate or necrotic. These changes can be initiated by damage to the cartilage directly, or indirectly, by lesions in the synovium.

Matrix metalloproteinases are enzymes capable of matrix digestion; they are normal constituents of the matrix, but are present in an inactive form. Matrix metalloproteinases can be broadly categorized as gelatinases, collagenases, and stromelysins. Collagenases are most capable of digestion of collagen fibers; gelatinases digest type I collagen and basement membrane collagens but are less effective against type II collagen of cartilage. Stromelysins destroy noncollagenous proteins. Matrix metalloproteinases can be activated by products of degenerating or reactive chondrocytes and inflammatory cells. In addition to acting as a control on the destructive effects of activated metalloproteinases, tissue inhibitors of metalloproteinases (TIMPs) are present in the matrix.

1058

**Fig. 16-30 Schematic diagram showing the structural changes that characterize fibrillation and eburnation of articular cartilage overlying subchondral bone.** In the area of eburnation, the cartilage is missing, and the exposed subchondral bone has increased density.

**Fig. 16-31 Fibrillation and ulceration, degenerative joint disease, tibia, proximal articular cartilage, sagittal section, bull.** To the left, the cartilage is frayed (fibrillation) and its surface has the appearance of a shag rug. To the right of the fibrillated region is an ulcer. Note that the cartilage is missing from the bed of the ulcer in the plane of the section, but the edge of the ulcer with a rim of normal cartilage is visible at its back. The cartilage to the right of the ulcer is very thin, indicating erosion. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

The loss of proteoglycans from cartilage alters the hydraulic permeability of the cartilage, thereby interfering with joint lubrication and leading to further mechanically induced injury to the cartilage. The loss of proteoglycans, with subsequent inadequate lubrication of the articular surface, leads to disruption of collagen fibers on the surface of articular cartilage. The surfaces of affected areas of cartilage are yellow-brown and have a dull, slightly roughened appearance. As more proteoglycans are lost, the collagen fibers condense and fray (fibrillation) with multiple clefts and/or fissures forming along the vertical axis of

## Pathologic Basis of Veterinary Disease, 4th Edition

the arcades of collagen fibers (Figs. 16-30 to 16-32). The vertical axis of the collagen fibers in these arcades is perpendicular to the plane of movement of the joint. Fibrillation is accompanied by loss of surface cartilage (erosion) and eventual thinning of the articular cartilage. Subsequent to fibrillation and erosion, necrosis of individual chondrocytes occurs in the radial zone, thus making cartilage hypocellular. In response to the fibrillation, erosion, and necrosis of chondrocytes, remaining chondrocytes can undergo regenerative hyperplasia (cluster or clone formation), but the ability of chondrocytes in the adult to divide is limited and the regenerative attempt is almost always ineffective. Loss of articular cartilage can become complete with exposure of subchondral bone (ulceration) (Fig. 16-33).

**Fig. 16-32 Degenerative joint disease, hip dysplasia, femoral head, articular cartilage, dog.** The superficial cartilage is fibrillated and hypocellular (necrosis) with clusters of chondrocytes (*arrows*) representing ineffectual attempts at repair. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

### 16.1.4.2 ARTICULAR CAPSULE/SYNOVIUM/SYNOVIAL FLUID

Intraarticular prostaglandins, nitric oxide, TNF- $\alpha$ , IL-1, and neurotransmitters—such as substance P among other cytokines and chemokines—are increased in degenerative and inflammatory joint disease. Prostaglandins and nitric oxide inhibit proteoglycan synthesis in synovium and chondrocytes; this reduction in proteoglycan content can lead to degeneration and loss of the cartilage (see previous discussion). IL-1 and TNF- $\alpha$  are cytokines secreted by activated macrophages (synovial type A cells or subintimal macrophages); they promote secretion of prostaglandins, nitric oxide, and neutral proteases from synovial fibroblasts and chondrocytes. Increasing concentrations of these agents will decrease matrix synthesis and increase matrix destruction. Cytokines and growth factors that can be anabolic to cartilage include IL-6, TGF- $\beta$ , and insulin-like growth factor.

## Pathologic Basis of Veterinary Disease, 4th Edition

Lysosomal enzymes (collagenase, cathepsins, elastase, arylsulfatase) and neutral proteases, which are capable of degrading proteoglycans or collagen, can be derived from inflammatory cells, synovial lining cells, and chondrocytes.

The synovial membrane commonly responds to injury by villous hypertrophy and hyperplasia, hypertrophy and hyperplasia of synoviocytes (Fig. 16-34), and pannus formation (see later discussion). Villous hypertrophy occurs with and without synovitis. The proportions of A and B cells in the synovium also can change in various disease processes. Fragments of articular cartilage can adhere to the synovium, where they are surrounded by macrophages and giant cells. Larger pieces of detached cartilage (as in osteochondrosis) can float free and survive as “joint mice” that continue to be nurtured and remain viable by synovial fluid.

1059

1060

**Fig. 16-33 Degenerative joint disease, hip dysplasia, bone, femur, head, dog.** The femoral head viewed from the medial aspect (A) and sagittal plane (B). The head is flattened (modeled) and ulcerated. The ulcerated region appears darker because congestion of blood vessels in the marrow spaces of the subchondral bone is visible through the thinned articular cartilage of the femoral head. The zone of attachment of the round ligament to the head of the femur has been destroyed. (A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Inflammatory cell infiltrates (see later section under Inflammatory Lesions: Infectious and Noninfectious Arthritis) in the synovial membrane can impair fluid drainage from the joint, and joint fluid can lose some of its lubricating properties because hyaluronic acid can be degraded by the superoxide-generating systems of neutrophils.

**Fig. 16-34 Synovial villous hyperplasia, hip dysplasia, coxofemoral joint, articular capsule and femoral head, dog.** There is marked villous synovial hyperplasia. The extent of this proliferation is unusually severe for hip dysplasia. Microscopically, this hyperplasia is routinely accompanied by variable lymphoplasmacytic inflammation that is independent of the cause of the articular damage. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-35 Pannus, rheumatoid-like arthritis, radius and ulna, proximal end, dog.** Note the fibrovascular tissue (pannus) covering all articular surfaces. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Pannus can develop in association with chronic infectious fibrinous synovitis and with some immune-mediated diseases, such as rheumatoid arthritis. Pannus is a fibrovascular and histiocytic tissue that arises from the synovial membrane and spreads over articular cartilage as a velvety membrane (Figs. 16-35 and 16-36). In the pannus, tissue histiocytes and monocytes of bone marrow origin transform into macrophages, and they, along with the collagenases from fibroblasts, cause lysis of cartilage (Fig. 16-37).

1060

1061

As the pannus spreads, the underlying cartilage is destroyed. In time, if both opposing cartilaginous surfaces are involved, the fibrous tissue can unite the surfaces, causing fibrous ankylosis (fusion of the joint). In some cases of immune-mediated arthritis, pannus is present in the subchondral bone marrow as well as in the synovium. Pannus can develop in marrow from subchondral bone and penetrate into the overlying articular cartilage.

**Fig. 16-36 Pannus, rheumatoid-like arthritis (experimentally induced), articular cartilage, tibia, distal end, rat.** The experimentally induced rheumatoid-like arthritis was produced by injecting Freund's adjuvant and *Mycobacterium butyricum* into the subcutis at the base of the tail. The pathogenesis of "adjuvant arthritis" is uncertain, other than it appears to be T-lymphocyte mediated. Here, fibrovascular repair tissue (pannus) is seen arising from the synovium (*left*) and growing onto the surface of the articular cartilage. There is not yet any damage to the cartilage beneath the pannus. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Fig. 16-37 **Pannus, rheumatoid-like arthritis (experimentally induced), articular cartilage, tibia, distal end, rat.** Pannus originating from the synovium (*right*) is invading and destroying the articular cartilage and bone. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Fig. 16-38 **Osteophytes, degenerative joint disease, distal femur, dog.** Note the marked formation of osteophytes (*arrows*) at the lateral and medial margins of the trochlear ridges. (Courtesy Dr. H. Liepold, College of Veterinary Medicine, Kansas State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Sterile degenerative changes in articular cartilage are often accompanied by the formation of periarticular osteophytes (Fig. 16-38) and by some degree of secondary synovial inflammation and hyperplasia. The synovitis is characterized by the presence of variable numbers of plasma cells, lymphocytes, and macrophages in the synovial subintima (beneath the layers of synoviocytes) and by hyperplasia and hypertrophy of synovial lining cells. The pathogenesis of this synovitis is not known, but is suspected to be secondary to release of sequestered or altered host antigens by the degenerate cartilage osteophytes that form as multiple bony or cartilaginous outgrowths. They can arise from mesenchymal cells with chondro-osseous potential within the synovial membrane at the junction of the synovial membrane with the perichondrium/periosteum, just peripheral to the articular cartilage or on the surface of the bone where the articular capsule and the periosteum merge. Osteophytes do not grow continuously, but once formed, they persist as multiple periarticular spurs of bone. These spurs can be confined within the joint cavity if they arise from the perichondrium or can be protrusions from the periosteal surface of the bone if they arise from the insertion site of the joint capsule with the periosteum. Osteophytes can result from mechanical instability within the joint causing stretching or tearing of the insertions of the articular capsule or ligaments, or they can form from stimulation by cytokines such as TGF- $\beta$  released from reactive or degenerating mesenchymal cells within the joint.

Because of their antiinflammatory effect, glucocorticoids are injected into joints. Sometimes this is followed by a rapid progression of degenerative changes within the joint and is designated “steroid arthropathy.” These degenerative changes relate to the antianabolic effects of glucocorticoids on chondrocytes. They reduce the synthesis of cartilaginous matrix, lead to proteoglycan depletion, retard repair, and reduce the mechanical strength of cartilage.

1061

1062

### 16.1.4.3

#### SUBCHONDRAL BONE

With loss of proteoglycans, concussive forces are less attenuated by degenerate or thin articular cartilage and a greater component of these forces then is transmitted to the subchondral bone. The bone responds to the increased mechanical use by decreasing resorption and increasing formation resulting in denser (sclerotic) bone. If the cartilage ulcerates to the level of the bone and the joint is still used, the dense bone can become polished and ivory-like (eburnation) (Fig. 16-33, A). There is interest in the possible role subchondral bone might play in initiating cartilage damage in degenerative joint disease. Overweight human beings (and animals) are predisposed to develop degenerative joint disease. In the human knee, the density of the subchondral bone is greater in overweight people presumably in response to increased weight bearing. This change precedes the development of degenerative joint disease. Some believe this dense bone is less effective in dissipating normal concussive forces and causes some of the impact to be deflected back into the articular cartilage causing injury to the chondrocytes.

### 16.1.5

#### PORTALS OF ENTRY INTO BONE

Infectious agents can enter bone directly through the periosteum and cortex or by the blood stream. Agents can gain access through the periosteum by means of trauma that may or may not break the bone or by extension from adjacent inflammation, as in periodontal tissue (periodontitis becoming a mandibular or maxillary osteomyelitis) or the middle ear (otitis media extending into the bone to become an osteomyelitis of the tympanic bulla). Blood vessels gain access to the marrow cavity of the diaphysis and metaphysis by the nutrient foramen. The epiphysis in the young animal depends mostly on the epiphyseal artery and small branches of that artery that cross the epiphyseal cortex. Blood-borne bacterial infection of bone in the perinatal animal may originate from the umbilicus or oral-pharyngeal route, with the latter being more likely. In theory,

## Pathologic Basis of Veterinary Disease, 4th Edition

hematogenous osteomyelitis can begin in any capillary bed in bone where bacteria lodge and survive. In practice, it occurs most commonly in young animals and is localized typically at the zone of vascular invasion of the growth plate (either at the physis [Fig. 16-39] or AE complex [Fig. 16-40]) where capillaries make sharp bends to join medullary veins (Fig. 16-12). Here, bacterial localization is apparently facilitated by slow flow and turbulence of blood in the larger descending limbs, a lower phagocytic capacity, and discontinuous endothelial cells. No vascular anastomoses are located in this region, and thrombosis of these capillaries results in bone infarction that is a predisposing factor for bacterial localization. It is likely that ligand-receptor binding between bacteria and endothelial cells plays a role. From this nidus at the physis or AE complex, the exudates can extend into other structures. At the AE complex the inflammation can extend into the overlying joint cavity (Fig. 16-40). At the physis, the inflammation can extend into the epiphysis, periosteum, or joint cavity (Figs. 16-41 and 16-42).

**Fig. 16-39 Embolic (suppurative) osteomyelitis and physitis, bone, radius, distal end, foal.** The pale region in the metaphysis extending upward to the top middle border of the illustration represents suppurative inflammation and necrosis. It is bordered by a red rim of active hyperemic. A fissure (*the linear and horizontal space on the metaphyseal side of the growth plate*) and the porosity (*darker regions within the growth plate, right*) are the result of bone lysis (primary trabeculae) caused by the physitis. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

### 16.1.6 PORTALS OF ENTRY INTO JOINTS

Microbial and other agents enter the joints via hematogenous spread and direct extension (Fig. 16-43). Neonatal bacteremia secondary to omphalitis or oral-intestinal entry commonly leads to polyarthritis. Bacteria can also reach the joint by direct inoculation, as in a puncture wound, by direct extension from periarticular soft tissues, or by extension from adjacent bone.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 16.1.7 DEFENSE MECHANISMS OF BONE

The defense against infectious agents is no different in bone than in other tissue. However, the consequences of an inflammatory response can have great effect on the structure and function of bone. Many soluble inflammatory mediators can increase both bone formation and resorption, resulting in varying extent of reactive bone formation and bone lysis. The exudate associated with some acute infections in the medulla can increase the pressure in the marrow cavity and cause compression of the nutrient artery resulting in ischemic necrosis. If resorbed cortical bone is replaced by scar tissue (fibrous repair tissue), the bone can become unstable.

1062

1064

**Fig. 16-40 Embolic (suppurative) osteomyelitis, bone, distal femur, medial trochlear ridge, transverse section, horse. A, Oblique view of articular cartilage and transverse section. B, The suppurative osteomyelitis has extended from its site of origin in the cancellous bone into the articular epiphyseal complex and then into the overlying articular cartilage, with resulting collapse and fragmentation of the articular cartilage. (A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)**

**Fig. 16-41 Schematic diagram showing patterns of spread of embolic osteomyelitis from the physis.** The septic embolus lodges in capillary loops at the physis (**A**). The inflammation causes lysis of metaphyseal bone and growth plate cartilage. This lysis can cause mechanical instability to which the periosteum responds by producing reactive bone (**B**). The exudates can lyse the cortex at its thinnest point (the metaphyseal cut back zone) and extend into the periosteum (periostitis) or into the joint (arthritis) (**C** and **D**). (**A** through **D**, Redrawn from Rubin *E: Essential pathology*, ed 3, 2001, Lippincott Williams & Wilkins).

(From Huether SE, McCance KL: Understanding pathophysiology, ed 2, St Louis, 2000, Mosby.)

### 16.1.8 DEFENSE MECHANISMS OF JOINTS

The cellular and humoral defenses against infectious agents are no different in the joint from those in other tissue. Details are presented previously in response to injury and later in the presentation of lesions in infectious and noninfectious arthritis. However, because articular cartilage has such limited ability to regenerate, the consequences of inflammation that destroy the ability of synovium to provide nutrients and synovial fluid to the cartilage or that destroy areas of the cartilage itself could progress to degenerative joint disease after the inflammation subsides.

### 16.2 DISEASES OF BONE

#### 16.2.1 ABNORMALITIES OF GROWTH AND DEVELOPMENT

##### 16.2.1.1 DISORDERS OF BONE RESORPTION

Osteopetrosis is an osteosclerotic (increased bone density per unit area) disease that occurs in dogs, sheep, horses, cattle, and several strains of mice and is described by some as a “metaphyseal dysplasia.” The basic disorder is due to failure of osteoclasts to resorb bone. The nature of the osteoclast failure has been defined in several strains of mice with spontaneous disease. In addition, knockout mice have been useful in defining

## Pathologic Basis of Veterinary Disease, 4th Edition

possible mechanisms for osteosclerosis, including knockouts for genes that encode for osteoclast differentiation factor and tartrate resistant acid phosphatase (an osteoclast lysosomal enzyme). The specific osteoclast defects are not yet known in domestic animals with osteopetrosis.

Growth plate: There are no primary lesions in the growth plate in osteopetrosis.

Trabecular bone: Osteoclasts are unable to resorb and shape (model) the primary trabeculae (Fig. 16-44). As a result, spicules of bone with central cores of calcified cartilage fill the medullary cavity. This process affects all bones that develop in a cartilaginous model (elongate by endochondral ossification from a growth plate). Affected bones are dense and have no medullary cavity. The rare disease has been reported in a variety of domestic and exotic animals. The defect in Angus cattle is inherited as an autosomal recessive trait. Affected calves are typically stillborn a few weeks premature and also have brachygnathia inferior, impacted molar teeth, and deformed cranial vaults that compress the brain.

Cortical bone: The cortical bone is essentially normal. The cut back zone of the metaphysis, although not as acutely angled as normal, is still present indicating periosteal osteoclast function might be less affected.

1064

1065

**Fig. 16-44 Osteopetrosis, bone, femur, calf (Aberdeen Angus). A,** The primary trabeculae are retained and fill the entire medullary cavity. **B and C,** Retained straight unremodeled trabeculae with cartilaginous cores fill the medullary (marrow) cavity. 16.2.1.2

### DISORDERS OF BONE FORMATION

Osteogenesis imperfecta is an osteopenic (reduced bone mass) disease and has been described in calves, lambs, and puppies; it involves bone, dentin, tendons, and sclera. Clinically, affected animals may have multiple fractures, joint laxity, and defective dentin. The basis of the lesion is a defect in osteoblastic and/or

## Pathologic Basis of Veterinary Disease, 4th Edition

---

odontoblastic production of type I collagen and in some cases decreased synthesis of certain noncollagenous proteins (i.e., osteonectin). In human beings, and likely in animals, the disease is mostly due to mutations in one or both of the genes that code for type I collagen. In cases in which errors are not found in the collagen genes themselves, alterations should be looked for in genes for enzymes responsible for posttranslational modification of collagen. Mild forms of the disease, because of inactivation of an allele of one of the genes, result in normal collagen but in reduced amounts. Mutations that cause substitutions in critical amino acids necessary for collagen helix formation and cross-linking can result in structurally inferior collagen that can be produced in normal amounts. It is interesting that the clinical manifestations of these mutations are usually limited to the bone, teeth, and eyes, even though type I collagen is the major structural collagen in the skin as well.

**Growth plate:** Growth plates are not affected in osteogenesis imperfecta and would not be expected to be because cartilage collagen is mostly type II.

**Trabecular bone:** In severe cases, there is much less trabecular bone than normal and without evidence of marked osteoclastosis or proliferation of fibrous tissue, as might be expected in severe cases of fibrous osteodystrophy (see later discussion). Osteoblasts can appear normal or small. In some cases, the amount of bone and its microscopic appearance is normal, but there is evidence of fracture disease. Fractures can be present at birth, some with callus formation indicating in utero fractures. Bone fragility in cases with normal bone mass and appearance is likely because of errors in helix formation or cross-linking of tropocollagen molecules. Calves with notable bone fragility (evidence of preparturition and postparturition fractures) can have bone that is normal microscopically and without obvious reduction in bone mass. These calves become osteopenic, possibly secondary to decreased mechanical use because of bone pain from fractures.

**Cortical bone:** There is a delay in the compaction of cortical bone. Compaction is the term used for the process of completing the formation of cortical bone during development. Depending on the species, varying size and contoured spaces are left between laminae or spicules of woven bone in the developing cortex. The filling of these spaces by bone to solidify the cortex is called compaction. The cortices in osteogenesis imperfecta can be composed of spicules or layers of woven bone with large vascular spaces remaining unfilled by bone. If the animal survives, these vascular spaces may eventually fill in with bone and form compact cortical bone.

1065

1066

**Teeth:** Because at birth bones can be structurally normal other than the presence of fractures, examination of teeth can be important in reaching a diagnosis of osteogenesis imperfecta morphologically. Grossly, teeth can be pink due to the visibility of the dental pulp through the thin crown. Histologically the dental tubules are short, tortuous, and sometimes absent. The disorganization of the dentin is a qualitative change that allows confirmation of the diagnosis without needing a control animal.

### 16.2.1.3 DISORDERS OF BONE MODELING

#### 16.2.1.3.1 Congenital Cortical Hyperostosis

Congenital cortical hyperostosis is an autosomal recessive inherited disease of newborn pigs (an example of diaphyseal dysplasia) characterized by the abnormal periosteal bone formation on major long bones. Lesions can be a consequence of disorganization of the perichondral ossification groove (the chondrogenic membrane surrounding the growth plate that enables the growth plate to expand in

## Pathologic Basis of Veterinary Disease, 4th Edition

diameter). One or several limbs can be affected. Piglets are stillborn or die shortly after birth because of other defects. The pathophysiology of the bone lesions is not understood.

Growth plate: Growth plates are not involved.

Trabecular bone: Trabecular bone is not involved.

Cortical bone: Cortical bone only is affected by the production of spicules of woven bone radiating outwards from the periphery of the preexisting cortex. These spicules are oriented perpendicular to the long axis of the cortex and arise from the cambium layer of the periosteum and other than extent of the change, is typical of the nonspecific reaction of the periosteum to injury described previously. The underlying cortex is normal.

### 16.2.1.3.2

#### Craniomandibular Osteopathy

Craniomandibular osteopathy, also known as “lion jaw,” typically occurs as an autosomal recessive condition in West Highland white terriers. Lesions like those in this breed have been reported as isolated occurrences in other breeds and have been associated with a leukocyte adhesion deficiency (suggesting an infectious cause) in a litter of Irish setter pups that also had lesions of hypertrophic osteopathy (see later discussion under noninfectious inflammation of bone). Lesions are bilaterally symmetric, resulting in overall irregular thickening of the mandibles, the occipital and temporal bones, and, occasionally, other bones of the skull (Fig. 16-45). The tympanic bullae are often severely affected. Less commonly the disease can affect the appendicular skeleton. The disease often becomes apparent at 4 to 7 months of age and can regress. For affected dogs, mastication is painful and difficult, and the muscles of the skull become atrophic from disuse. The etiopathogenesis of this disease is unknown. A similar self-limiting disease has recently been reported in the calvaria of young bull mastiffs.

**Fig. 16-45 Craniomandibular osteopathy, bone, skull, dog (West Highland white terrier).** Extensive periosteal new bone formation on the lateral surfaces of the body and ramus of the mandible, caudolateral maxilla, bulla tympanica, and occipital condyle. Macerated and bleached specimen. (Courtesy Dr. H. Leipold, College of Veterinary Medicine, Kansas State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Growth plate: Growth plates are not involved.

Trabecular bone: In the medullary cavities of the bones of the skull and jaw, trabeculae become osteosclerotic (increased bone density per unit area) because of proliferation of woven bone by the osteoblasts of the endosteum with subsequent modeling and remodeling (see next discussion on cortical bone).

Cortical bone: In the skull and jaw, the cortices are thickened because of proliferation of woven bone by the periosteum. Characteristic of the disease is rapid disorganized modeling and remodeling of this bone, causing a mosaic of reversal cement lines with regions of lamellar bone adjacent to regions of woven bone.

### 16.2.1.4 DISORDERS OF ENDOCHONDRAL OSSIFICATION

#### 16.2.1.4.1 Chondrodystrophies

Chondrodystrophies are disorders of bone growth as a result of primary lesions in growth cartilage. Growth cartilage includes the physis, AE complex and epiphyseal cartilage (articular epiphysal yet to undergo endochondral ossification [AE complex] as the secondary center of ossification expands).

1066

*Chondrodystrophy* generally implies a widespread abnormality of growth cartilage but could be expressed only in the AE complex selectively affecting the epiphysis (epiphyseal dysplasias such as spider lamb in Suffolk and Hampshire sheep) or only in the physis (metaphyseal dysplasias such as chondrodysplasia in the Alaskan malamute, Norwegian elkhound, and Great Pyrenees breeds). Chondrodystrophies can result in dwarfism. Affected animals usually are short-legged with normal-sized heads because the bones of the calvarium (but not the maxilla and mandible) arise from membranous bone rather than endochondral bone. These are called disproportionate dwarfs. Proportional dwarfism is usually due to underlying endocrine disease (pituitary dwarfism) or malnutrition.

1067

The mechanisms of chondrodysplasias in animals is rarely determined, but defects can be caused by inherited errors in genes that control chondrogenesis. In human beings, the most common dwarfism is called achondroplasia (a misnomer because growth cartilage is present). The condition is inherited as an autosomal dominant trait caused by a single point mutation in the fibroblast growth factor receptor 3 (FGFR3) gene. This mutation results in constant activation of this receptor causing down-regulation of chondrocyte proliferation.

Skeletal dysplasias have also been reported in animals with inherited lysosomal storage diseases, such as mucopolysaccharidosis and gangliosidosis. Chondrocytes can be vacuolated because of retained glycosaminoglycans and lipid.

Growth plate: Growth plates can appear normal or thin depending on the disease. Likewise the arrangements of the chondrocytes can be in normal columns or markedly disorganized. The cartilage matrix can appear normal or rarified.

Trabecular bone: The primary trabeculae can be reduced in amount with the cartilage cores being coarse and misshaped rather than fine regular spicules. This can vary greatly with the type of chondrodysplasia.

Cortical bone: Lesions in cortical bone are greatly variable and mostly due to abnormality in shape or size. Little would be learned from microscopic examination of cortical bone.

### Osteochondrosis

The osteochondroses consist of a heterogeneous group of lesions in growth cartilage of young animals and are characterized by focal or multifocal failure (or delay) of endochondral ossification. As such, osteochondrosis involves the metaphyseal growth plate and the AE complex. The lesions are common and represent an important orthopedic entity that has a number of different clinical manifestations in pigs, dogs, horses, cattle, poultry, and rats. Many investigators have made the point that the term “osteochondrosis,” which implies degeneration of cartilage and bone, is inappropriate because the lesions are initially in the cartilage. The hallmark of the uncomplicated gross lesions of osteochondrosis is focal or multifocal retention of growth cartilage due to its failure to become mineralized and replaced by bone (a failure of endochondral ossification).

The cause of osteochondrosis is unknown. The high incidence of osteochondrosis in species bred and fed to achieve maximal body weight at a young age suggests that it might be a mechanical complication superimposed on minor multifocal defects of endochondral ossification that occur normally. Presumably, uneven patterns of endochondral ossification are common, and most go undetected. Only in animals selected for rapid weight gain might these develop into clinically significant lesions. Little evidence is available to indicate that the lesions of osteochondrosis result from a specific nutritional deficiency. However, copper deficiency, perhaps induced by excess dietary zinc, has produced lysis of the AE complex and formation of thin flaps of cartilage in thoroughbred suckling foals. Also, lesions of cartilage retention are less frequent in foals from mares fed increased dietary copper. Osteochondrosis-like lesions have been reported at greater incidence in growing dogs fed high-calcium diets.

Not only are the causes of osteochondrosis unknown, but the nature of the initial lesion in areas of dysplasia is still under debate. Necrosis of cartilage in the epiphysis of the pig, likely secondary to ischemia from physiologic thrombosis of cartilage vessels, might contribute to lesions of osteochondrosis in the AE complex. Studies examining the role of apoptosis in the development of osteochondrosis in poultry have revealed contradictory findings.

Foci of retained cartilage in the physis or AE complex can be unrelated to osteochondrosis and can be secondary to anything that will interfere with vascular invasion of the cartilage, such as infractions (fractures without affecting the external contour of the bone) of the primary trabeculae or inflammation.

The simplest forms of osteochondrosis have been called dysplasias of the physis and AE complex.

Growth plate: Grossly the dysplasia is usually a well-demarcated wedge of white, firm hyaline cartilage at the AE complex or physis (Fig. 16-46). Variations in this gross appearance might reflect stages of resolution or secondary necrosis. Hemorrhage and mineralized debris can occur at the junction of the dysplastic and adjacent bone. Often small dysplastic areas produce no clinical signs. Such dysplasias are common, especially in the distal femurs of pigs; the distal femur, distal tibia, and vertebral articular facets of horses; the proximal humerus of dogs; and the proximal tibia of rapidly growing birds.

1067

1068

Microscopically, these areas are composed of hypertrophic, sometimes poorly aligned chondrocytes without evidence of mineralization or vascular invasion (Fig. 16-47). Particularly in horses, acellular streaks are present within the cartilage. Microscopically, these streaks are eosinophilic due to loss of proteoglycans and condensation of the collagen fibers. Sometimes splitting of the condensed collagen occurs causing fissures within the streaks (Fig. 16-47). These streaks might be sequelae to physiologic necrosis of chondrocytes that can occur when blood vessels that extend across the growth plate undergo normal thrombosis. These streaks are found in normal cartilage, but they can appear exaggerated in some

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cases of osteochondrosis. Dysplasias can progress, spontaneously resolve by endochondral ossification, or undergo necrosis and cavitation.

**Fig. 16-46 Dysplasia of the articular-epiphyseal complex, bone, distal femur, lateral trochlear ridge, horse.** The cartilage extending into the epiphysis is from epiphyseal cartilage that has failed to undergo endochondral ossification and been retained as cartilage, whereas the remainder of the epiphysial cartilage has been converted to bone. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Trabecular bone:** Immediately subjacent to a dysplastic area, the trabeculae are usually coarse, modeled, and without cartilage cores. Often due to the failure of endochondral ossification, there is some discontinuity between the retained cartilage and the bone; this space is occupied by slight fibrosis. If the dysplastic areas are large and became necrotic, a cystic space filled with serumlike fluid and lined by fibrous tissue can form in the metaphysis.

**Cortical bone:** Lesions in cortical bone are not expected with dysplasias of osteochondrosis, but dysplasias of the physis can cause angular limb deformities as a result of uneven longitudinal growth. This condition of angular limb deformity subsequent to lesions in the growth plate or primary trabeculae is sometimes lumped under the term “epiphysitis” in horses. Epiphysitis in horses can be due to true dysplasias of osteochondrosis or can be secondary to trauma or inflammation of the growth plate and/or primary trabeculae.

**Fig. 16-47 Dysplasia of the articular-epiphyseal complex, bone, distal femur, lateral trochlear ridge, horse.** Note the retained cartilage outlined by arrowheads; it has no evidence of vascular invasion. There are numerous eosinophilic streaks (*arrows*), which sometimes contain cavitations. The cause and significance of these streaks and cavities are uncertain. Because the specimen was decalcified for ease of sectioning, it cannot be used to confirm that mineralization is absent H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

16.2.1.4.3

### Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is the name given to dysplasias at the AE complex that form clefts in the retained cartilage with subsequent fracture of the overlying articular cartilage (Fig. 16-48). The result is a cartilaginous or osteochondral flap, depending on the extent of bone that is associated with the cartilage. Should this flap fracture off and become free in the joint space, it is called a “joint mouse.” OCD can be accompanied by pain, joint effusion, and nonspecific secondary lymphoplasmacytic synovitis. Free-floating joint mice occasionally interfere with mechanical movement of the joint. The lesions of OCD develop in various synovial joints, including those of the facets of the vertebral column. Common sites of OCD are the humeral head in the dog, the anterior aspect of the intermediate ridge of the distal tibia in horses, and the medial condyles of the distal femur and distal humerus in pigs. The disease is a significant cause of lameness in young breeding pigs. The articular cartilage defect in OCD might never heal, and such joints are destined to develop some degree of degenerative joint disease.

1068

Fig. 16-48 **Osteochondritis dissecans (osteochondrosis), bone, articular cartilage, humerus, proximal end, dog.** A flap of cartilage with articular-epiphyseal complex dysplasia (not visible from this view of the surface) has detached from the underlying bone. The synovium is hyperemic and hyperplastic. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Fig. 16-49 Dysplasia of the articular-epiphyseal (AE) complex, osteochondritis dissecans (osteochondrosis), bone.** **A**, Humerus, pig. The retained cartilage has separated from the subchondral bone (*arrows*) but a fissure has not formed to the articular surface. **B**, AE complex, femur, distal end, horse. A linear fissure between the dysplastic AE complex and underlying (subchondral) bone is extending into adjacent normal (*right*) articular cartilage. H&E stain. **C**, Humerus, horse. Note the fissure within the region of the AE complex. A preexisting dysplasia is not obvious. H&E stain. (**A and B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University. **C**, Courtesy Dr. C. Bridges, College of Veterinary Medicine, Texas A&M University; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Growth plate: For the development of OCD, clefts must develop in dysplasias at the AE complex (Fig. 16-49). These clefts can be linear and be formed by necrosis of cartilage, possibly induced by pressure or failure of nutrient diffusion, or they may be consequences of eosinophilic streaks as described previously. Cleft formation can cause mechanical instability and lead to separations within cartilage or between cartilage and the underlying bone. Trauma can cause the cleft to extend through the overlying articular cartilage, resulting in the formation of a flap.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lesions of OCD can develop in horses without predisposing dysplasias (retention of growth cartilage). In these cases, articular cartilage of normal thickness can be peeled from the subjacent bone because of fissuring in the deeper layers of the AE complex. Such lesions have been seen in foals licking fences with zinc-based white paint. The pathogenesis of the lesion is thought to involve copper deficiency induced by the zinc excess. Copper is a required cofactor for enzymes that facilitate cross linkages between tropocollagen molecules, but these foals do not appear to have any generalized collagen dysplasia. In addition, a relatively common and often clinically incidental lesion of lysis of the AE complex cartilage without flap formation is seen in articular facets of 1- to 2-year-old horses. In such cases there is coagulation necrosis of the AE complex of inapparent cause and no dysplasia. There is a fissure formed, but the overlying articular cartilage usually does not fracture free to form a flap.

1069

1070

Trabecular bone: Changes in trabecular bone of the epiphysis reflect the extent of the cleft formation and whether the flap detached. Marked fibrosis and formation of reactive woven bone is expected at the base of the flap.

Cortical bone: Lesions in cortical bone are not expected with OCD.

16.2.1.4.4

### Epiphysiolysis

Epiphysiolysis is the separation of the epiphysis from the metaphysis because of fissure formation horizontally through the physis. This is not associated with focal or multifocal dysplasia and because of that is different from the osteochondroses presented previously (other than that seen in foals with zinc toxicity). The condition is most common in pigs and dogs. The femoral head can be involved in market-weight pigs and in young gilts. In young sows, separation of the ischial tuberosity at its growth plate is a common cause of caudal weakness and inability to stand. In dogs, the process of epiphysiolysis can affect the anconeal process of the ulna (united anconeal process). Epiphysiolysis is the only form of osteochondrosis found in the cat. In the cat, a diffuse physeal dysplasia with slipped capital femoral epiphysis is described in heavy young adult castrated male cats. The growth plates in these cats appears to remain open longer than expected and might, along with weight, be a predisposing factor for lesion development.

Growth plate: Grossly there is a horizontal fissure/fracture through the physis with complete or partial separation of the epiphysis from the metaphysis. The growth plate may be delayed in closing and have fewer chondrocytes than expected with their arrangement being somewhat disorganized.

Trabecular bone: The response to trabecular bone in epiphysiolysis is that expected from trauma and fracture. There is marrow fibrosis and proliferation of reactive woven bone with variable hemorrhage in the marrow cavity.

Cortical bone: There are no primary changes in cortical bone with this condition, and any lesions that would develop would be secondary to altered mechanical use.

16.2.1.4.5

### Cervical Vertebral Myelopathy

Cervical vertebral myelopathy (CVM) is secondary to static or dynamic compression on the spinal cord by abnormal cervical vertebrae. The abnormal vertebrae can cause this compression constantly as a result of an absolute stenosis of the canal or intermittently during movement (usually flexion). It is useful therefore to try to determine clinically if the lesion represents a static compression or dynamic

## Pathologic Basis of Veterinary Disease, 4th Edition

compression. Clinical localization of the lesion by neurologic examination, myelography, or computerized tomography is very helpful to the pathologist. The condition is seen most often in horses and giant breed dogs. In thoroughbred and standard bred horses and in dogs, the static compression is usually due to a grossly appreciable narrowing of the spinal canal from caudal to cranial within a single vertebral body (Fig. 16-50). The pathogenesis of this is not known but is likely developmental. In quarter horses, localized hyperplasia and fibrocartilaginous metaplasia of the ligamentum flavum (the ligament between the dorsal lamina), likely secondary to chronic mechanical irritation and/or trauma, can protrude into the spinal canal and cause static compression of the spinal cord.

The lesions associated with dynamic compression of the cord are more variable and less definitive because often identical lesions can be found in asymptomatic animals. In horses, the most common lesions are those of osteochondrosis (see previous discussion) of the cervical facets. Osteochondrosis can cause abnormal and asymmetric development of the facets or abnormally large cranial epiphyses of the vertebral bodies. With each of these, it is possible that during flexion, the dorsal aspect of the vertebral body compresses the ventral aspect of the cord, causing transient ischemia. Such compression can at first cause functional deficits only without lesions in the spinal cord, but can progress to notable Wallerian degeneration. Horses with clinical signs of dynamic cervical vertebral myelopathy have the same frequency of osteochondrosis in the cervical vertebrae as clinically normal horses, but the severity of the lesions are worse in clinically affected horses. In addition, the diameter of the vertebral canal is smaller in affected horses, suggesting that compression of the cord in these horses would be easier to achieve. The frequency and severity of osteochondrosis lesions in the appendicular skeleton are greater in horses with clinical signs suggesting a systemic condition.

1070

1071

**Fig. 16-50 Static stenosis, bone, cervical vertebra, sagittal section, horse.** Static stenosis (narrowing) of the vertebral canal due to malformation of the vertebra (*bottom vertebra*). Note the smaller diameter of the vertebral canal at the cranial end (*arrows*) of this vertebra. The top vertebra is normal. (Courtesy College of Veterinary Medicine University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 16.2.2 METABOLIC BONE DISEASES

These systemic skeletal diseases are generally of nutritional, endocrine, or toxic origin (Tables 16-1 and 16-2). Structural abnormalities occur in both growing and adult skeletons during normal modeling and remodeling. Metabolic bone diseases are often called osteodystrophies. The term “osteodystrophy” is a general one and implies defective bone formation. The classical metabolic osteodystrophies are osteoporosis, fibrous osteodystrophy, rickets, and osteomalacia. These terms imply specific pathologic changes but do not necessarily imply a specific cause. For example, osteoporosis can be due to a calcium deficiency, glucocorticoid therapy, or physical inactivity. Different osteodystrophies can coexist in the same skeleton. For example, the skeleton of an animal with a severe calcium deficiency accompanied by excess dietary phosphorus might have features of both osteoporosis and fibrous osteodystrophy. In practice, most nutritional deficiencies in domestic animals do not involve a single element; more often, deficiencies are multiple, not severe, and not the “classic” lesions produced under experimental conditions.

Table 16-1 Metabolic Bone Disease

Disease	Characteristics	Causes
Osteoporosis	Reduced bone mass—porous, thin, and brittle bones	Protein calorie malnutrition, immobilization, dietary calcium deficiency, glucocorticoid excess, menopause in human beings
Osteomalacia (adult animals)	Decreased bone mineralization (accumulation of osteoid)—soft bones	Vitamin D deficiency, phosphorus deficiency
Rickets (growing animals)	Decreased bone mineralization (accumulation of osteoid)—soft bones; thickened growth plates (failure of endochondral ossification)	Vitamin D deficiency, phosphorus deficiency
Fibrous osteodystrophy	Decreased bone mass because of resorption and replacement by fibrous tissue, rubbery bone	Hyperparathyroidism <ol style="list-style-type: none"><li>1. Primary—functional chief cell adenoma of parathyroid gland</li><li>2. Paraneoplastic—parathyroid hormonelike—related protein from neoplasia-like adenocarcinoma of apocrine glands of anal sac</li><li>3. Secondary nutritional hyperparathyroidism from diets low in calcium and high in phosphorus</li><li>4. Secondary renal hyperparathyroidism from failure of the kidney to secrete phosphorus and reduced synthesis of 1,25-dihydroxyvitamin D</li></ol>

#### 16.2.2.1 OSTEOPOROSIS

Clinically, osteoporosis is the disease of bone pain and fracture secondary to a reduction in bone density or mass (Fig. 16-51). The bone present, although reduced in amount, is normally mineralized. When there is reduced bone mass but no clinical disease, the term *osteopenia* is more appropriate. If the disease progresses and clinical signs appear, the disease is called osteoporosis. Osteopenic bone lacks strength and is more easily fractured. In senile osteoporosis in human beings, in addition to decreased bone density, the

1071

## Pathologic Basis of Veterinary Disease, 4th Edition

---

turnover rate is reduced, allowing microcracks (small cracks in the bone visible only microscopically) to accumulate. These microcracks superimposed on the reduced bone mass make bones more brittle than would be predicted from the reduced mass alone. In growing animals, osteoporosis is potentially reversible. In adults, however, once trabecular bone is lost, it is very slow to be replaced physiologically. For some locations, such as the femoral neck, trabecular bone contributes much to the bone's strength. In the femoral diaphysis, it is the thickness and density of the cortex that determine strength. Some of the causes of osteopenia include calcium deficiency, starvation, physical inactivity, and the administration of glucocorticoids. A calcium deficiency can result in hypocalcemia, which is compensated for by increased PTH output and increased bone resorption. It is not clear why calcium deficiency does not result in fibrous osteodystrophy, as described later. Starvation and malnutrition can result in arrested growth and osteoporosis, largely because of reduced bone formation because of deficiencies of protein and mineral.

1072

Reduced physical activity (disuse or immobilization osteoporosis) causes increased bone resorption and decreased bone formation. This disuse loss of bone might be mediated through changes in piezoelectrical activity, streaming potentials, and stretch receptors that are able to detect decreased mechanical use of the skeleton. Loss of bone mass associated with long-term paralysis or immobilization is not necessarily progressive; rather, the skeleton stabilizes at a new (reduced) level. Postmenopausal osteoporosis is a common and important disease in women; it often results in vertebral deformity or collapse and pathologic fractures of the femoral neck. Declining concentrations of estrogens, physical inactivity, reduced muscle tone, and inadequate calcium intake are factors that can be responsible for causing osteopenia to progress to osteoporosis. Estrogen generally potentiates bone formation and inhibits bone resorption, likely by altering cytokine production from osteoblasts and monocytes. Estrogens promote secretion of TGF- $\beta$  (an anabolic cytokine) and decrease production of IL-1, IL-6, and TNF- $\alpha$  (cytokines that promote osteoclasts). The loss of estrogen in menopause will have the opposite effect. IL-6 knockout mice do not get osteopenia following ovariectomy, confirming the critical role of cytokines in this process. Interestingly, ovariectomy in the bitch is not associated with clinical osteoporosis. In experimental studies, a transient osteopenia has been found in ovariectomized dogs; these studies confirm years of veterinary clinical observations that spayed dogs are not at risk to develop osteoporosis. Osteopenia associated with reduced estrogens from ovarian atrophy or ovariectomy appears to be greatest in animals with estrous cycles that extend throughout the year (e.g., rat, pig, and primate).

1072

1073

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 16-2 Toxic Osteodystrophies

Principal	Route/Source	Lesions	Mechanism
Vitamin D	Ingestion of plants (e.g., <i>Solanum malacoxylon</i> ) that contain water-soluble glycosides of the vitamin; ingestion of excess vitamin D added to Feed	Acute high-dose exposure: widespread soft tissue mineralization  Chronic lower dose exposure: osteosclerosis with formation of abnormal woven bone matrix with increased basophilia	Acute high dose: increased absorption of calcium from intestines and increased release by osteoclasts from bone  Chronic lower dose: suppression of bone resorption by hypercalcemia, which suppresses parathyroid hormone and increases calcitonin secretion Vitamin D also likely has direct stimulatory effect on osteoblasts
Vitamin A	Ingestion of excessive retinoids (not carotenoids) as found in certain plants (sweet potatoes) and meat (liver) or drug toxicity	Growing animals: multifocal premature closures of growth plates with subsequent growth deformity, osteoporosis, and pathologic fractures Adult animals: osteosclerosis, periosteal bone formation, and exostoses	Retinoids cause degeneration and necrosis of chondrocytes and osteoblasts in growing animals and paradoxically are stimulatory to osteoblasts in adult animals
Lead	Ingestion usually from licking lead-based paint	Characteristic lesion is a "lead line," an osteosclerotic band of bone parallel to the growth plate; osteoclasts can have acid-fast lead inclusions; osteoporosis also can be present, but likely secondary to systemic illness of lead toxicity	Lead is stored in bone mineral; part of the sclerosis seen radiographically is a result of the radiodensity of the lead; lead is toxic to osteoclasts; bone mineral with lead is somewhat resistant to osteoclasts
Fluoride	Ingestion of rock phosphates naturally high in fluoride; grazing on pastures with naturally high fluoride soil content or contaminated with fluoride as industrial by product; drinking water with naturally high fluoride content	Chronic low toxic levels cause osteosclerosis; chronic higher toxic levels cause osteopenia and periosteal bone formation	At lower toxic levels fluoride is stimulatory to osteoblasts and its incorporation in the hydroxyapatite make the crystal more resistant to resorption At higher toxic levels the mechanisms are uncertain, but direct toxic injury to osteoblasts is possible, resulting in osteopenia with the periosteal proliferation; begins a reaction to support the mechanically weakened skeleton

**Fig. 16-51 Osteoporosis, bone, cervical vertebrae, median section, horse.** Note the markedly thin cortices, particularly the dorsal ones. The thickness of trabeculae has been reduced, but this is difficult to appreciate. The vertebra to the right has a compression fracture, seen as collapsing of the trabeculae into each other, shortening of the length of the body between the growth plates and buckling of the ventral cortex. The marrow has been flushed from the specimen for purposes of illustration of the bone changes. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Growth plate:** Lesions in the growth plate are not expected in osteoporosis unless the disease is related to pituitary dysfunction or protein calorie malnutrition, in which the plate would be thin.

**Trabecular bone:** Trabeculae become thinner, become fewer in number, and develop perforations within the plates. With time the normal structure of trabecular bone (anastomosing plates) is replaced by strut or rodlike bone. The loss of these anastomoses results in reduced ability of the trabeculae to withstand stress. In most long bones of adults, trabeculae extend from the epiphysis to the metaphyseal-diaphyseal junction. The degree to which the trabeculae do not reach this distance suggests the extent of the osteopenia (Fig. 16-52, A).

**Cortical bone:** Cortical bone becomes thin because of osteoclastic resorption on the endosteal surface with corresponding enlargement of the medullary cavity. The cortex becomes porous because of increased resorption within the cortical vascular spaces and Haversian systems and/or decreased osteoblastic activity (Fig. 16-52, B). In severe cases, cortices become brittle, and the force required to break them is notably reduced.

**Fig. 16-52 Osteopenia, bone, metatarsal, sheep.** **A**, There is marked reduction in the number and length of trabeculae. **B**, The cranial cortex (*right*) is markedly porous, and the caudal cortex (*left*) is thin. The marrow has been flushed from the specimen for purposes of illustration of the bone changes. (**A and B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

16.2.2.2

### RICKETS AND OSTEOMALACIA

Failure of mineralization with subsequent bone deformities and fractures is called rickets in the growing skeleton and osteomalacia (soft bone) in the adult. In the immature animal, rickets is a disease of bone and cartilage undergoing endochondral ossification. In the adult, osteomalacia is a disease only of bone. Clinically, affected animals have bone pain, pathologic fractures, and deformities such as kyphosis and scoliosis.

The most common causes of rickets and osteomalacia are deficiency of vitamin D or phosphorus. However, failure of mineralization and rickets and/or osteomalacia can occur in chronic renal disease and in chronic fluorosis. Dietary phosphorus deficiency is not common but can occur in herbivores grazing on phosphorus-deficient pastures. Phosphorus-deficient animals often have reduced feed intake, are unthrifty, and have impaired reproductive performance. Vitamin D deficiency is rare today because this vitamin is

## Pathologic Basis of Veterinary Disease, 4th Edition

---

commonly added to commercial feed, and animals exposed to adequate sunlight should be able to synthesize their own if they have normal kidneys. It is not clear why phosphorus deficiency and vitamin D deficiency cause osteomalacia and calcium deficiency does not. An observation to further complicate the issue is that knockout mice with no receptors for vitamin D get rickets, but this can be corrected by feeding a high-calcium diet. Apparently, in the distal small intestine, calcium absorption is passive and not vitamin D dependent. This suggests that vitamin D deficiency causes rickets as a result of reduced intestinal absorption of calcium and adds to the confusion over why dietary calcium deficiency does not result in rickets. Species variation is important in this matter. In fact, birds will get ricketslike lesions with calcium deficiency, but this is not the case with mammals.

**Growth plate:** The growth plates in rickets are thickened because of failure of mineralization ([Fig. 16-53](#)). The costal-chondral junctions can be prominent and nodular, and historically the lesion has been called “rachitic rosary” because of its resemblance to a string of prayer beads. This thickening is apparent grossly as retained cartilage. Microscopically the columns of chondrocytes in the plate are disorganized. In mammals, there is a marked increase in the number of chondrocytes in the zone of proliferation compared with normal. This is presumably due to the inability of these proliferating chondrocytes to mature. It is uncertain if the disorganization of chondrocytes in vitamin D-deficiency rickets is due to a primary effect of vitamin D metabolites (specifically, 24,25-dihydroxyvitamin D) or a mechanical consequence of the failure of endochondral ossification. Because of the inadequate absorption of calcium in rickets, the growth plate does not undergo mineralization. In mammals, when mineralization of the cartilage matrix does not occur, blood vessels with accompanying chondroclasts do not invade the physis. Because the ability of the chondrocytes to proliferate and hypertrophy is at least partially retained in rickets, the growth plate thickens because the rate of its removal by endochondral ossification is reduced.

**Fig. 16-53 Vitamin D deficiency (experimental), bone, tibia, chicken.**

Left specimen—rachitic tibia; middle and right specimens—normal chicken and a chicken fed a vitamin D deficient diet supplemented with calcitriol. The latter two specimens appear normal and are indistinguishable from each other. In these normal-appearing bones, notice the tapering of the metaphysis (“cutback” zone) and the thickness of the growth plate. In these normal chickens, the cleft (*arrows*) separating the growth plate from the epiphyseal cartilage is an artifact. There is no ossification center present in the epiphysis, which is normal for young broilers. The growth plate in the rachitic bird is thickened. The arrowhead indicates the junction between the growth plate and the epiphyseal cartilage. The metaphysis has not undergone modeling (“cutback”). H&E stain. (*Courtesy Dr. L. Nagode*).

**Trabecular bone:** Grossly and radiographically the metaphyses are “flared” in rickets because of failure of bone and cartilage removal in the cutback zones (Fig. 16-53). Poorly mineralized matrixes cannot be resorbed because osteoclasts cannot bind to an unmineralized matrix (see previous discussion). Microscopically the surfaces of trabecular bone in rickets and osteomalacia have excessive amounts of osteoid (unmineralized matrix) (Fig. 16-54). Osteoclasts are not able to adhere to, or resorb, osteoid. Therefore bone modeling and remodeling is impaired. Hypocalcemia can develop in a vitamin D deficiency, and lesions of secondary hyperparathyroidism (fibrous osteodystrophy [see later discussion]) also can develop.

**Cortical bone:** Grossly cortical bone can be of normal appearance or the softened bone can be deformed by weight bearing. In severe cases, the bones are so soft that they can be cut with a knife. Microscopically, endocortical and trabecular surfaces in the cortex can have numerous wide seams of unmineralized osteoid. Osteomalacic bone is susceptible to accumulation of microcracks because of the impaired remodeling and modeling secondary to osteoid surfaces interfering with osteoclasts.

1074

**Fig. 16-54 Osteomalacia, bone, cross section, metaphysis, trabeculae, human being.** This person had osteomalacia secondary to malabsorption of fat soluble vitamins (including vitamin D) associated with gastrectomy. This section was not demineralized and was stained to show the difference between osteoid (*red*) and fully mineralized bone (*blue-green*). Normally no more than 10% of trabecular surfaces should be covered by osteoid seams, but in this case almost all surfaces are covered by osteoid. Goldner's trichrome stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

### 16.2.2.3 FIBROUS OSTEODYSTROPHY

Fibrous osteodystrophy is the name given to the skeletal lesions of increased widespread osteoclastic resorption of bone and replacement by fibrous tissue because of primary, secondary, and pseudohyperparathyroidism. Weakening of bones leads to lameness, pathologic fractures, and deformities. As described previously, osteoblasts—but not osteoclasts—have receptors for parathyroid hormone and respond by up-regulating production of osteoclast differentiation factor and down-regulating secretion of osteoprotegerin. Bone marrow stromal cells also have receptors for parathyroid hormone, and when the hormone is expressed constantly at high levels, these cells differentiate into fibroblasts. Paradoxically, intermittent doses of parathyroid hormone have the opposite effect on bone. Daily injections of parathyroid hormone is, as of this writing, the most potent inducer of new bone formation in women with advanced stages of postmenopausal osteoporosis.

In domestic animals, primary hyperparathyroidism, as in cases of functional parathyroid adenoma, parathyroid carcinoma, or idiopathic bilateral parathyroid hyperplasia, is rare. Secondary hyperparathyroidism is more common and can be either nutritional or renal in origin (nutritional or renal

## Pathologic Basis of Veterinary Disease, 4th Edition

fibrous osteodystrophy). Nutritional hyperparathyroidism is caused by dietary factors that tend to decrease the concentration of serum ionized calcium, to which the parathyroid glands respond by increasing output of PTH. It is most common in young, growing animals that are fed rations deficient in calcium and have a relative excess of phosphorus. Unsupplemented cereal grain rations fed to pigs, all-meat diets fed to dogs and cats, and bran fed to horses are examples of low-calcium, high-phosphorus diets that can cause secondary nutritional hyperparathyroidism and eventually fibrous osteodystrophy. Increased concentrations of dietary phosphorus are important in the evolution of fibrous osteodystrophy, perhaps by interfering with the intestinal absorption of calcium.

Growth plate: No primary lesions are expected in the growth plate or AE complex.

Trabecular bone: Trabeculae are thinned by osteoclastic resorption. Osteoblastic proliferation can be marked but ineffectual in that they produce little osteoid. Proliferation of fibrous tissue in the marrow space is usually marked but in early stages can be subtle and consist of only two or three layers of cells between the bone lining cells and the marrow space (Fig. 16-55). In severe cases, the marrow cavity is obliterated by fibrous tissue.

Cortical bone: Bone resorption and replacement by fibrous tissue can be so extensive that the bone becomes pliable (Fig. 16-56). Clinically and at postmortem examination, in severe cases bones can be bent at a right angle without fracture. Osteoclastic resorption begins on the endocortical bone surface, but any vascular spaces within the wall of the bone can undergo marked enlargement by osteoclastic resorption and replacement by fibrous tissue. In advanced disease, entire cortices can be replaced by reactive woven bone and fibrous tissue. Sometimes the proliferation of fibrous tissue is exuberant and associated with increased external dimension of the bone (Fig. 16-57). This process is more common in the maxilla and mandible and might reflect the response of the weakened bone to the intense mechanical stress of mastication.

1075

1076

**Fig. 16-55 Tunneling resorption (within a trabecula), fibrous osteodystrophy, bone, longitudinal section, dog.** Osteoclasts (*right*) have resorbed the central portion of the trabecula, and this space is being replaced by fibrous tissue rather than bone, as in normal remodeling. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-56 Fibrous osteodystrophy, bone, maxillae and mandible, transverse section, dogs.** **A**, The pliable nature of the bone can be seen by the collapsed and folded (not fractured) appearance of the nasal septum and maxilla. **B**, Radiograph. There is marked loss of bone density around the teeth in both maxillae and mandibles. These changes are detectable only by radiographic examination. (*A and B, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

### 16.2.2.4 RENAL FIBROUS OSTEODYSTROPHY

Renal fibrous osteodystrophy is a general term that refers to the skeletal lesions that develop secondary to chronic, severe renal disease. Osteomalacia and fibrous osteodystrophy can occur as separate diseases or in combination as a result of chronic renal disease in human beings. Fibrous osteodystrophy, which is sometimes complicated by osteomalacia, occurs in the dog, the animal most commonly affected with renal osteodystrophy. Dogs can have bone pain (lameness) and loss of teeth and deformity of the maxilla or mandible because of the osteoclastic resorption of bone and replacement by fibrous tissue. The pathogenesis of renal osteodystrophy is complex and likely varies depending on the extent and nature of the renal disease and the availability of dietary vitamin D. Loss of glomerular function, inability to excrete phosphate, inadequate production of 1,25-dihydroxyvitamin D by the kidneys, and acidosis are central to the development of renal osteodystrophy. Phosphate retention because of decreased renal excretion leads to hyperphosphatemia. As the calcium and phosphorus product exceeds solubility, calcium is precipitated in soft tissue resulting in hypocalcemia. This hypocalcemia stimulates PTH output with subsequent fibrous osteodystrophy. The reduced production of 1,25-dihydroxyvitamin D by the diseased kidneys together with impaired mineralization because of the acidosis of uremia explain the development of osteomalacia.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 16.2.3 INFLAMMATION OF BONE

#### 16.2.3.1 INFECTIOUS INFLAMMATION OF BONE

Inflammation of bone is called osteitis, periostitis if the periosteum is involved, and osteomyelitis if the medullary cavity of the bone is involved (Table 16-3). These can be common and sometimes life threatening and require early diagnosis and vigorous treatment. Osteomyelitis is often a chronic, disfiguring process caused by necrosis and removal of bone and by the compensatory production of new bone; the two processes often proceed simultaneously over a prolonged period. Osteitis is often a painful process leading to debilitation of the affected animal. Infectious inflammation of bone in animals is usually caused by bacteria, although viral, fungal, and protozoal agents can be involved. Hematogenous bacterial osteomyelitis is uncommon in dogs and cats, but it is common in neonatal animals used for food and fiber production and foals. A wide range of gram-positive and gram-negative bacteria is responsible for hematogenous osteomyelitis in calves and foals. *Arcanobacterium pyogenes* and other pyogenic bacteria (e.g., *Streptococcus* spp., *Staphylococcus* spp.) and *Salmonella* spp., *Escherichia coli*, and other coliforms are among the most common microbes that cause hematogenous osteomyelitis. *Staphylococcus intermedius* is the most common cause of hematogenous osteomyelitis in the dog.

1076

1077

**Fig. 16-57 Fibrous osteodystrophy, bone, maxillae and mandibles. A,** Nutritional fibrous osteodystrophy, horse. Note the swelling of the facial crest. **B,** Maxillae, cross section, horse. Proliferating and poorly organized fibroosseous tissue in the maxillae has distorted and extended their contours laterally and compressed the nasal cavity medially. Note the absence of normal bone. **C,** Renal fibrous osteodystrophy, dog. Exuberant poorly mineralized woven bone and fibrous tissue has caused the maxillary bones to expand and distort the positioning of the teeth. Similar changes affect the mandible, and its teeth are also malpositioned. **D,** Radiograph, renal fibrous osteodystrophy, dog. Postmortem transverse slab section demonstrating the reduced bone density (radiodensity) of the proliferated woven bone and fibrous tissue that has replaced the preexisting maxillary bones. Note the absence of normal radiodense bone. (**A and D,** Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University. **B,** Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C,** Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Fungi and viruses also can cause disease in bone. Mycotic agents such as *Coccidioides immitis* and *Blastomyces dermatitidis* are frequently spread hematogenously to bone to produce granulomatous or pyogranulomatous osteomyelitis, with bone lysis and irregular new bone formation. Various viral agents also localize in bone. The viruses of hog cholera and infectious canine hepatitis can cause endothelial damage, resulting in metaphyseal hemorrhage and necrosis, and acute inflammation. Osseous localization of the distemper virus injures osteoclasts, disrupting metaphyseal modeling and producing a growth retardation lattice as described earlier. A variant of the feline leukemia virus has been associated with myelosclerosis (increased density of medullary bone) in cats. These latter two viruses do not cause an inflammation of bone.

1077

1078

**Table 16-3 Lesions of Inflammatory Joint Disease**

	Synovial Fluid	Location Synovial Membrane	Articular Cartilage
<b>TIME/EXUDATE</b>			
Acute suppurative	Reduced viscosity Neutrophils	Hyperemia Edema	No lesions
Subacute suppurative	Reduced viscosity Neutrophils	Hyperplasia Lymphoplasmacytic Inflammation	Usually no lesions
Chronic suppurative	Reduced viscosity Neutrophils	Hyperplasia Lymphoplasmacytic inflammation Fibrosis	Erosion Ulceration

Subacute fibrinous	Reduced viscosity Fibrin	Hyperplasia Lymphoplasmacytic Inflammation	Usually no lesions
Chronic fibrinous	Reduced viscosity Fibrin	Hyperemia Lymphoplasmacytic Fibrin Pannus	Erosion Ulceration Pannus

Growth plate: Epiphyseal cartilage (Fig. 16-58) (cartilage of the epiphysis that has yet to undergo endochondral ossification) and physeal cartilage can be eroded by invasion of inflammation from adjacent bone or direct bacterial embolization in the blind-loop vessels at sites of endochondral ossification (see portals of entry section). In contrast to cartilage lysis, it is possible for growth cartilage to appear thickened, secondary to osteomyelitis caused by disruption of endochondral ossification by the inflammatory process and failure to replace cartilage with bone. In growing animals, articular cartilage can be lysed by extension of osteomyelitis from the subjacent AE complex, so what appears to be a primary arthritis actually began in the underlying epiphysis.

Trabecular bone: The composition of the exudates in metaphyseal osteomyelitis is determined by the infectious agent, but in bacterial infection in domestic animals it is typically purulent. Exudate in the medullary cavity increases the intramedullary pressure and can cause compression of vessels resulting in thrombosis and infarction of intramedullary fat, hematopoietic marrow, and bone. Thrombosis of vessels and local tissue infarction are important in the evolution of bacterial osteomyelitis. In areas of inflammation, bone resorption is mediated mostly by osteoclasts stimulated by prostaglandins and cytokines released by local tissue and inflammatory cells. Reduced blood flow through large vessels also promotes osteoclastic bone resorption, possibly by altering electrostatic charges in bone. In addition, proteolytic

1078

## Pathologic Basis of Veterinary Disease, 4th Edition

enzymes released by inflammatory cells and activation of matrix metalloproteinases by the acid environment of inflammation assist in resorbing matrix. Lack of drainage and persistence of the offending agent in areas of necrotic bone account for the chronicity of the process. Bacteria can persist for years in cavities and areas of necrosis in bone. Inflammation in the medullary cavity can penetrate into and through cortical bone and undermine the periosteum, where it can further disrupt the blood supply to the bone at the nutrient foramen and nutrient canal.

1079

**Fig. 16-58 Emboli (suppurative) epiphysitis, bone, femur, distal end, foal.** Bacterial emboli in the articular-epiphyseal complex have produced suppurative inflammation that has destroyed both the subchondral bone and overlying articular cartilage of the condyle (right). (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-59 Chronic (suppurative) osteomyelitis, bone, mandible, transverse section, sheep.** Chronic suppurative osteomyelitis has caused a fistulous tract that penetrates through the full dorso-ventral thickness of the mandible. This lesion likely began as a periodontal bacterial infection. The ventral progression of the lesion reflects the effects of gravity on the exudate. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Fig. 16-60 Chronic (pyogranulomatous) osteomyelitis and sinusitis, actinomyces (*Actinomyces bovis*), maxillary sinus, cow. A,** Transverse section of the maxillae. The nodules apparent within the masses in the sinuses and maxilla represent pockets of pyogranulomatous inflammation that are surrounded by fibrous tissue and woven bone. **B,** Macerated and bleached specimen of the mandible. Note the spicules of woven bone radiating from the mandible. Within the spaces formed by this reactive bone were nodules of pyogranulomatous inflammation and colonies of *Actinomyces bovis*. (**A and B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Cortical bone: The lesions in cortical bone with infectious osteomyelitis can vary with the route of entry of the organism and the nature of the exudates (Fig. 16-59). With suppurative inflammation, bone lysis is expected. The lysis would be subperiosteal for bacteria induced traumatically by way of the periosteum and endosteal in cases of embolic osteomyelitis. Lysis within the cortex begins within existing vascular channels and can occur with either route of entry. Periostitis can develop by direct inoculation from trauma (e.g., puncture wounds) or by centripetal spread from the marrow cavity and through the cortex. Chronic bacterial periostitis is characterized by multiple spreading pockets of exudates and areas of irregular periosteal new bone formation and cortical lysis (Fig. 16-60). Additional sequelae of osteomyelitis include extension of inflammation to adjacent bone, hematogenous spread to other bones and soft tissue, pathologic fractures, and development of sinus tracts that penetrate cortical bone and drain to the exterior.

Occasionally, fragments of dead bone become isolated from their blood supply and surrounded by a pool of exudates (bone sequestrum). Sequestra can form when bone fragments are contaminated at the site of a compound fracture, when the fragments at a fracture site become infected hematogenously, or when fragments of necrotic bone become isolated and thus avascular in osteomyelitis (Fig. 16-61). These isolated

1079

1080

## Pathologic Basis of Veterinary Disease, 4th Edition

fragments of bone (sequestra) and associated exudates can become surrounded by a dense collar of reactive bone (the involucrum). Extracellular matrix is not living tissue. With the death of the cells in the bone and marrow space, there is no way for the bone matrix to be resorbed from within bone (matrix devoid of cells will not liquefy). Therefore relatively large sequestra can persist for long periods and interfere with repair. They often become pale and chalky and lack the glistening appearance of normal bone.

**Fig. 16-61 Suppurative periostitis and osteomyelitis, phalanges, horse.**

Trauma to the dorsal aspect of the hoof inoculated bacteria into the subcutis, causing suppurative cellulitis and periostitis and, subsequently, cortical osteolysis of the dorsal aspect of the distal first phalanx and the entire dorsal surface of the second phalanx. From there, the infection spread to the distal interphalangeal joint and then to the third phalanx, where it caused suppurative osteomyelitis, loss of articular cartilage, and formation of a sequestrum in the proximal portion of the third phalanx (*arrow*). The viable tissue immediately adjacent to the sequestrum is not different from that further away, implying that in this case an involucrum (reactive bone surrounding the exudate around a sequestrum) was not formed. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Fig. 16-62 Hypertrophic osteopathy, bone, distal radius, dog.** **A**, Radiograph. The radiolucent line (*arrow*), parallel with the level of the primary trabeculae, is characteristic of hypertrophic osteopathy. **B**, Grossly, this line appears to be a fracture within the metaphysis, parallel with the growth plate. The zone of primary trabeculae is more visible in the radiograph than in this gross specimen. **C**, Histologically, this line is a hypercellular band (\*) of neutrophils between the primary and secondary trabeculae. (**A**, **B**, and **C**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

### 16.2.3.2 NONINFECTIOUS INFLAMMATION OF BONE

#### 16.2.3.2.1 Hypertrophic Osteodystrophy

Also termed metaphyseal osteopathy, hypertrophic osteopathy is a disease of young, growing dogs of the large and giant breeds. These names are unfortunate because they are misleading. The initial lesions are those of a suppurative and fibrinous osteomyelitis of the trabecular bone of the metaphysis. The cause and pathogenesis are unknown; infectious agents have not been isolated. There have been reports of hypertrophic osteopathy in litters of Weimaraners, in which granulocytopathies have been suspected, and in littermates of Irish setters, in which canine leukocyte adhesion deficiency was confirmed. This would suggest infectious agents in that these dogs are susceptible to infections, but the cause of the bone lesions was not determined in these reports. Clinically, hypertrophic osteopathy is characterized by lameness, fever, and swollen, painful metaphyses in multiple long bones.

Growth plate: Lesions in the growth plate are not expected in hypertrophic osteopathy.

Trabecular bone: Lesions are usually bilaterally symmetric. Radiographically, metaphyseal zones of increased lucency and increased density are adjacent and parallel to the physes (Fig. 16-62, A and B). Microscopically the lucent areas represent suppurative and fibrinous inflammation and necrosis of the metaphyseal marrow and bone (Fig. 16-62, C). The death of osteoblasts results in primary trabeculae that are not reinforced by apposition of bone matrix. These trabeculae collapse and fracture without external distortion of the bone (infractures) and appear radiographically as relatively dense regions.

Cortical bone: The inflammation can extend from the medulla through the cutback zone into the periosteum. This periosteal inflammation, along with mechanical instability due to the metaphyseal infractures can cause notable new metaphyseal periosteal bone formation in chronic cases.

### 16.2.3.2.2

#### Eosinophilic Panosteitis

Eosinophilic panosteitis is another canine bone disease with an unfortunate name. The lesion is neither inflammatory nor eosinophilic. The cause is not known, and the disease is almost always self-limiting. It occurs in growing (usually large-breed) dogs and is painful. Morphologic studies are few because the disease is easily recognized clinically and resolves spontaneously so that biopsy evaluation is rarely necessary. Radiographically the lesions are recognized as increased densities in the medullary cavity in the diaphysis, usually beginning near the nutrient foramen. Increased densities can also be present in the periosteum. These densities are due to proliferation of well-differentiated woven bone and fibrous tissue. No inflammation is present. The cause of the lameness is presumed to be pressure on nerves by the proliferating woven bone both within the medullary cavity and on the periosteum.

1080

1081

### 16.2.4

#### ASEPTIC NECROSIS OF BONE

Aseptic necrosis of bone in human beings occurs in a variety of clinical conditions, including occlusive vascular disease (bone infarction), hyperadrenocorticism, fat embolism, nitrogenous embolism, sickle cell anemia, and intramedullary neoplasms, all of which likely result in arterial or venous infarction of the bone (Table 16-4). In domestic animals, aseptic necrosis of bone has been associated with intramedullary neoplasms and various nonneoplastic lesions. Decreased venous outflow from the bone and increased bone marrow pressure are important factors in the pathogenesis of ischemic or aseptic necrosis of bone. The gross appearance of necrotic bone varies with its extent and the response to it. Microscopically the hallmark of bone necrosis is cell death and loss of osteocytes from their lacunae.

Following an episode of ischemia leading to infarction, the cellular elements of the marrow lose their differential staining, and circular spaces (pooled lipid) develop within a few days. If the region of dead bone remains avascular, the coagulated tissue and mineralized matrix can persist for some time. Dead osteocytes elicit little reaction; their nuclei become pyknotic, but their disappearance from lacunae is slow and might not be complete for 2 to 4 weeks.

Reaction to and repair of necrotic bone requires revascularization that is associated with infiltration of macrophages and invasion by fibrous tissue that advances from the margins of the lesion. The bone marrow might eventually regenerate entirely, or a scar might form and remain. The necrotic matrix remains fully mineralized and might even “hypermineralize” because of calcification of the dead osteocytes and their lacunae. This mineralization is only possible if there is vascularization that brings additional calcium to the region. Dead bone is slowly removed by osteoclasts. The resorption of necrotic bone with simultaneous

## Pathologic Basis of Veterinary Disease, 4th Edition

replacement by new bone is termed “creeping substitution.” The process is slow and often incomplete. Small areas of bone necrosis might not be detected clinically or radiographically.

Growth plate: Ischemic necrosis of metaphyseal bone and bone marrow can result in retained growth cartilage. The metaphyseal necrosis would not affect the zones of proliferating and hypertrophying chondrocytes, and the physal thickness would increase because its removal by endochondral ossification would be impaired. Ischemic necrosis of the epiphysis could result in premature closure of the growth plate because of death of the proliferating chondrocytes, which are dependent on the epiphyseal blood vessels. Endochondral ossification would continue normally if the metaphyseal blood supply is not affected, and the plate would close because of failure to replenish new chondrocytes.

1081

1082

**Table 16-4 Necrosis of Bone**

Cause/Duration of Necrosis	Lesion	Clinical Significance
Acute aseptic (ischemic) necrosis	Death of bone cells and marrow; bone structure intact	Can be clinically silent
Chronic aseptic (ischemic) necrosis	<p>1. If no revascularization, dead bone can remain intact structurally for a long time but will accumulate microcracks</p> <p>2. If revascularization takes place, dead bone can be resorbed slowly and replaced by new bone</p> <p>3. If revascularization takes place, dead bone may be resorbed slowly and NOT be replaced by bone but by fibrous tissue</p>	<p>1. Can remain clinically silent, but risk of microcrack progressing to complete clinical fracture increases with time and mechanical use</p> <p>2. Can remain clinically silent from initiation of lesion to completion of repair</p> <p>3. Can cause structural failure and collapse of the bone (e.g., chronic idiopathic necrosis of the femoral head)</p>
Acute septic necrosis	Exudate, usually suppurative, will form at junction of dead bone and viable tissue with subsequent bone lysis and reactive bone formation	Pain due to cytokines from the inflammation and pressure in marrow cavity and periosteum
Chronic septic necrosis	<p>1. If the focus of dead bone is relatively small, it can be completely resorbed by the inflammatory process and osteoclastic bone lysis; there can be marked modeling of bone, usually with resorption predominating and replacement by fibrous tissue; in some cases excess formation can occur</p> <p>2. If the focus of dead bone is relatively large, it can be sequestered (sequestrum) by a peripheral wall of reactive fibrous tissue or reactive bone (involucrum)</p>	Pain due to cytokines and pressure in marrow cavity and periosteum; draining tracts can form; strength of the bone can be weakened because of resorption or its function can be affected by exuberant formation

Trabecular bone: In the femoral heads of young, small, and miniature breed dogs, aseptic necrosis of the femoral head is associated with clinical signs because of the collapse of the articular cartilage as a result of resorption of the necrotic subchondral bone (Legg-Calvé-Perthes disease) that occurs late in the course of the disease. Apparently the initial infarction is asymptomatic (Fig. 16-63). The cause of the infarction is usually not determined but might be caused by venous compression or increased pressure within the articular cavity. This pressure can result in increased intraosseous pressure and bone necrosis. In clinical cases of aseptic necrosis, the dead bone is not replaced by creeping substitution but is ultimately resorbed and replaced by fibrous tissue. The fibrous tissue does not provide adequate support for the articular cartilage, and the femoral

## Pathologic Basis of Veterinary Disease, 4th Edition

---

head collapses. In stages before complete resorption, it is common in revascularized necrotic medullary bone, for reactive new bone to be deposited on trabeculae of necrotic bone (Fig. 16-64). This sandwich of central dead bone covered by viable reactive woven bone can persist for months and give (along with osteocyte mineralization described previously) the affected region a radiodense appearance. Ultimately in clinical cases of aseptic necrosis of the femoral head, even these foci of new bone formed on top of dead bone are resorbed and replaced by fibrous tissue. Although the long-term use of steroids in human beings has been associated with necrosis of the femoral head in adults, steroids do not appear to induce osteonecrosis in domestic animals.

Cortical bone: Large areas of necrotic cortical bone have a dry, chalky appearance; the periosteum can be removed easily; and they can remain for years and be subclinical. The formation of sequestra almost always requires inflammation. Sequestra formation in sterile necrosis of bone is unlikely.

### 16.2.5 PROLIFERATIVE AND NEOPLASTIC LESIONS

Surprisingly, bone, as a tissue, offers little resistance to an expanding or invading neoplasm, and many skeletal neoplasms are accompanied by both bone resorption and new bone formation (Fig. 16-65). Pain, hypercalcemia, increased serum alkaline phosphatase activity, pathologic fracture, and distant metastases are other possible manifestations of a skeletal neoplasm. New bone formation occurs, at least in part, in response to mechanical stress on a weakened cortex and is prominent in neoplasms that have a marked fibrous stroma. Neoplasms with little stroma, such as plasma cell myeloma and lymphosarcoma, have minimal reactive bone formation, even though bone can be weakened by marked bone lysis. Tumor-associated bone destruction is largely accomplished by osteoclasts, but prostaglandins, cytokines, acid metabolic by-products, and lytic enzymes released by inflammatory or neoplastic cells can be responsible for local bone resorption and formation. Hypercalcemia, due in part to bone resorption induced by release of bone-resorbing factors from extraskelatal neoplasms, is well documented (humoral hypercalcemia of malignancy). In animals, the most common example is adenocarcinoma of the apocrine glands of the anal sac in the dog. This neoplasm produces PTH-related protein and it metastasizes widely, but rarely to bone.

1082

1083

**Fig. 16-63 Femoral head, necrosis (experimental), bone, femur, pig.**

Necrosis was produced experimentally by a ligature placed around the femoral neck. Several days after the procedure, the only difference between the control **(A)** and the infarcted bones **(B)** is the coagulation necrosis of the marrow and bone cells. The hard tissue of the cartilage and bone remains unaffected. H&E stain. (**A** and **B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Fig. 16-64 **Revascularization, ischemic necrosis (experimentally induced), 1-month duration, femoral head, epiphyseal (cancellous) bone, pig.** Reactive woven bone (*between arrows*) has been deposited on the surface of the necrotic bone. Empty lacunae and karyolytic nuclei in the bone indicate that it is necrotic. Fibrovascular repair tissue in the marrow surrounds the bone. H&E stain. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

16.2.6 NONNEOPLASTIC PROLIFERATIVE AND CYSTIC LESIONS

Lesions considered here vary widely in their cause, structure, and ultimate effect on the host. Reactive bone formation, sometimes exuberant, can occur in fracture repair, chronic osteomyelitis, and degenerative joint disease in the form of periarticular osteophytes. An exostosis or osteophyte is a nodular, benign, bony growth projecting outward from the surface of a bone. An enthesophyte is an osteophyte at the insertion of a ligament or tendon. In addition to bone, these proliferations can have variable amounts of cartilage. The bone

## Pathologic Basis of Veterinary Disease, 4th Edition

component can be woven and/or lamellar, depending on rate of growth and duration of lesion. Hyperostosis usually is used to indicate that the diameter of the bone has increased and implies more uniform thickening on the periosteal surface rather than the nodular appearance of an osteophyte. An enostosis is a bony growth within the medullary cavity, usually originating from the cortical-endosteal surface, and can result in obliteration of the medullary cavity. The above lesions are nonneoplastic proliferative lesions in which growth is seldom continuous. Some exostoses can remodel and some regress. Nonneoplastic proliferative lesions can be mistaken for skeletal neoplasia in some biopsy specimens. Conversely, small superficial biopsies might contain only nonneoplastic reactive bone overlying a malignancy. These statements serve to highlight the problem of making a morphologic diagnosis from a small biopsy specimen, without the benefit of a clinical history, radiographic findings, and other laboratory data. One must also remember that more than one process might be active at any one site (e.g., osteosarcoma might be complicated by fracture repair or by osteomyelitis).

Hypertrophic osteopathy (hypertrophic pulmonary osteopathy) occurs in human beings and in domestic animals, with the dog being the most commonly affected. The disease is characterized by progressive, bilateral, periosteal, new bone formation in the diaphyseal regions of the distal limbs (Fig. 16-66). The word “pulmonary” is included because most cases have intrathoracic neoplasms or inflammation. Other less commonly associated lesions or agents are endocarditis, heartworms, rhabdomyosarcoma of the urinary bladder in young giant-breed dogs, and ovarian neoplasms in the horse. Although the association between the pulmonary lesions and the proliferation of new periosteal bone on the extremities is not clear, it has been postulated that pulmonary lesions lead to reflex vasomotor changes (mediated by the vagus nerve) and to increased blood flow to the extremities. In hypertrophic osteopathy, woven bone is rapidly deposited by the periosteum of the diaphysis of the long bones. Similar periosteal woven deposition can occur in the metaphysis, but in hypertrophic osteopathy the lesions are usually less severe and less frequent in the metaphysis compared with the diaphysis. This periosteal new bone causes notable thickening of the limb bones. The lesions can regress if the primary lesion is removed. Regression of the bone lesions also occurs after vagotomy. Increased arterial pressure, hyperemia, and edema of the periosteum lead to thickening of the periosteum both by fibrous tissue and later by new bone formation. Lesions similar to hypertrophic osteopathy can be reproduced in dogs by creating shunts that allow blood to bypass the pulmonary circulation, thereby increasing the stroke volume of the left side of the heart and increasing the blood flow to peripheral tissue.

1084

1085

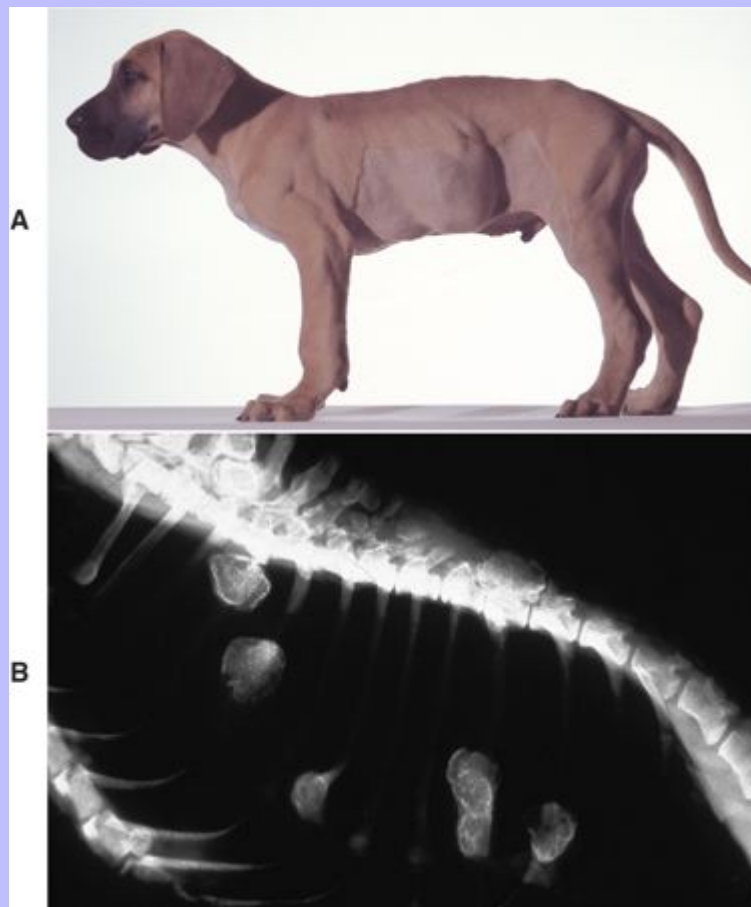

**Fig. 16-66 Hypertrophic pulmonary osteopathy, bone, radius and ulna, dog.** Marked periosteal proliferation of woven bone has caused a roughened irregular surface, particularly of the ulna. Macerated and bleached specimen. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Osteochondromas (multiple cartilaginous exostoses) occur in dogs and horses and reflect a defect in skeletal development rather than a true neoplasm. This condition is inherited and lesions appear shortly after birth. Osteochondromas project from bony surfaces as eccentric masses that are located adjacent to physes. They arise from long bones, ribs, vertebrae, scapulas, and bone of the pelvis and can be numerous (Figs. 16-67 and 16-68). Microscopically, they have an outer cap of hyaline cartilage that undergoes orderly endochondral ossification to give rise to trabecular bone that forms the base of the lesion (Fig. 16-68, C). The medullary cavity of the osteochondroma usually communicates with the medullary cavity of the underlying bone, because the cortex of the underlying bone at this site has not completely developed. Trabecular bone and bone marrow are continuous with those of the adjacent bone. Normally, growth ceases at skeletal maturity when the cartilage cap is replaced by bone. Although the origin of osteochondromas is not clear, some arise secondary to a defect in the perichondral ring as peripheral pieces of physal cartilage are pinched off and carried away from the growth plate by longitudinal growth. Clinically, their importance is threefold: They might interfere mechanically with the action of tendons or ligaments; they can act as space-occupying masses that protrude into the vertebral canal and cause spinal cord compression; and they can undergo malignant transformation and give rise to chondrosarcomas. Osteochondromas in cats are different in that they develop in mature animals, less commonly affect long bones, do not have orderly endochondral ossification, and might be of viral origin. Osteochondromas in cats, like those in horses and dogs, can undergo malignant neoplastic transformation. The term osteochondroma is sometimes used (but not recommended) for cartilaginous osteophytes that have undergone central endochondral ossification. As will be discussed in callus formation in fracture repair, the osteogenic tissue (cambium layer) of the periosteum can form hyaline cartilage instead of bone when the oxygen tension of the tissue is low.

Fibrous dysplasia is an uncommon focal to multifocal, lytic, intraosseous lesion that has been found at various sites (skull, mandible, and long bones) in young animals. It could be a developmental defect. Typically, preexisting bone is replaced by an expanding mass of fibro-osseous tissue that can weaken the cortex and enlarge the external contour of the bone. The lesion is firm, often has mineralized areas when sectioned, and can have multiple cysts filled with sanguinous fluid. Microscopically, well-differentiated fibrous tissue has relatively regularly spaced and sized trabeculae of woven bone. Osteoblasts are not recognizable on trabecular surfaces, a feature that helps to distinguish this lesion from ossifying fibroma.

Fig. 16-67 **Osteochondromas, young dog.** **A**, Multiple protruding nodules of osteochondromas (cartilaginous exostoses) are present as single and coalescing masses on the ribs. **B**, Radiograph. The cartilaginous exostoses have the density of bone and appear in this case as exophytic nodules on the ribs and the dorsal spinous processes of the vertebral bodies. (**A** and **B**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Bone cysts are classified as subchondral, simple, or aneurysmal. Radiographically, all appear as lucent areas without evidence of aggressive growth. Subchondral cysts are sequelae to osteochondrosis and degenerative joint disease. Subchondral bone cysts due to osteochondrosis represent failure of endochondral ossification with subsequent necrosis and cavitation of retained growth cartilage. Bone never was present in such lesions. Subchondral cysts secondary to degenerative joint disease represent herniation of synovial fluid into the subchondral bone through fissures in the articular cartilage. These herniations become lined by a synovial cell-like membrane. Bone lysis is by osteoclasia secondary to either pressure or cytokines released from the expanding cyst.

1085

1086

Fig. 16-68 **Osteochondromas (cartilaginous exostoses), bone, distal femoral metaphysis, dog.** **A**, A plateaulike mass (*left*) protrudes from the metaphyseal cortex. **B**, On cross section, the mass (*left*) has a cartilage cap. **C**, Histologically, the cartilage cap is undergoing endochondral ossification as would be seen in an articular-epiphyseal complex. H&E stain. (**A**, **B**, and **C**, Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

Simple bone cysts can contain clear, colorless, serumlike fluid, or the contents can be notably serosanguinous. The wall of the cyst is composed of variably dense fibrous tissue and woven to lamellar bone. Bone peripheral to this has undergone modeling to accommodate the expansile growth of the cyst. The category of simple bone cysts can overlap substantially with that of fibrous dysplasias; a clear distinction between them can be difficult to make.

Aneurysmal bone cysts consist of spaces filled with blood or serosanguinous fluid. Tissue adjacent to the spaces can vary from well-differentiated fibrous or fibroosseous tissue to pronounced proliferation of undifferentiated mesenchymal cells admixed with osteoclast-like multinucleated giant cells. Hemorrhage and

## Pathologic Basis of Veterinary Disease, 4th Edition

hemosiderosis are frequent. An endothelial cell lining is usually not present. The cause of simple and aneurysmal bone cysts is unknown. They could be consequences of ischemic necrosis, hemorrhage, or congenital or acquired vascular malformations. Caution should be exercised in the interpretation of microscopic lesions in biopsy specimens of cysts, and these lesions should be correlated with the radiographic appearance to rule out cystic cavitation in a neoplasm.

### 16.2.7 PRIMARY NEOPLASMS OF BONE

The histopathologic diagnosis of skeletal neoplasia in domestic animals often involves evaluation of needle, trephine, or wedge biopsies (Table 16-5). It is important that the pathologist be aware of the radiographic findings to determine if the biopsy is representative of the clinical process. Often biopsies consist only of reactive periosteal tissue, and if the lesion is both lytic and proliferative, the clinician should be told that the biopsy specimen is not likely representative of the entire mass. The pathologist must explain any conflicts between the interpretation of the biopsy and radiographic findings. Radiographically aggressive lesions with mass effect usually indicate malignancy or inflammation. If a lesion is radiographically aggressive, the pathologist should not definitively conclude that a process is benign based only on the microscopic findings unless there is an explanation of the aggressive appearance (e.g., secondary infection in a benign neoplasm; pathologic fracture).

1086

1087

Table 16-5 Primary Skeletal Neoplasms of the Dog

Name	Cell of Origin	Incidence	Primary Site	Biologic Behavior
Osteoma	Osteoblast	Rare	Flat bones	Benign
Osteosarcoma	Osteoblast	Common	Predominantly metaphyses of larger appendicular bones	Highly malignant with metastases early in clinical course
Chondroma	Chondroblast/chondrocyte	Rare	Flat bones	Benign
Chondrosarcoma	Chondroblast/chondrocyte	Relatively rare	Ribs, sternum, nasal cavity	Metastases not common and late in clinical course
Fibroma	Fibroblast			Not significantly recognized as a primary tumor of bone
Fibrosarcoma	Fibroblast	Relatively rare	Diaphysis of bones of appendicular skeleton	Metastases relatively late in clinical course

Ossifying fibromas are uncommon masses in the maxillae and mandibles of horses and cattle. In their early stages, these are intramedullary neoplasms. Although considered benign, they destroy adjacent cortical and trabecular bone by expansile growth. Microscopically, they are composed of well-differentiated fibrous tissue with scattered spicules of woven bone covered by osteoblasts.

Fibrosarcomas are malignancies of fibroblasts that produce collagenous connective tissue but not bone or cartilage. Microscopically the matrix of fibrosarcomas should not mineralize and entrap cells in lacunae as happens in normal and neoplastic bone and cartilage. Cells can be arranged in a whirling or interlacing pattern. Central fibrosarcomas arise from fibrous tissue within the medullary cavity, whereas periosteal fibrosarcomas arise from periosteal connective tissue. Central fibrosarcomas must be distinguished grossly and microscopically from osteosarcoma. In general, central fibrosarcomas grow more slowly, are accompanied by less formation of reactive new bone, are slower to metastasize, and produce a smaller tissue mass than

## Pathologic Basis of Veterinary Disease, 4th Edition

osteosarcomas. Grossly, fibrosarcomas are gray-white, fill part of the medullary cavity, and replace cancellous and cortical bone.

Chondromas are benign neoplasms of hyaline cartilage. They are very rare neoplasms of dogs, cats, and sheep and often arise from flat bones. Cartilaginous neoplasms in the skeleton do not arise from articular cartilage, most likely because of its low mitotic potential and avascularity. They are usually in adult animals that do not have growth cartilage, so the cell of origin is presumed to be a stromal cell with chondrogenic potential. Chondromas are multilobulated and have a blue-white cut surface. They tend to enlarge slowly but progressively and can cause thinning of underlying bone. Microscopically, they are composed of multiple lobules of well-differentiated hyaline cartilage. Endochondral ossification of the neoplastic cartilage is possible. They are difficult to distinguish from low-grade, well-differentiated chondrosarcomas. Chondromas that arise in the medullary cavity are called enchondromas.

Chondrosarcomas are malignant neoplasms in which the neoplastic cells produce cartilaginous matrix but not osteoid or bone. They are most common in mature dogs of the large breeds and in sheep. In sheep, they arise from the ribs and sternum; in dogs, the major sites of origin are the nasal bones, ribs, and pelvis. In general, chondrosarcomas most frequently arise in the flat bones of the skeleton (Figs. 16-69 and 16-70).

Chondrosarcomas can evolve from multiple cartilaginous exostoses in dogs and in human beings. Most arise in the medullary cavity and destroy preexisting bone. Given time, they become large, lobulated neoplasms with a gray or blue-white cut surface. Some neoplasms are gelatinous on sectioning, and some have large areas of hemorrhage and necrosis. Microscopically (Fig. 16-71) the range of differentiation of neoplastic cells is wide: Some neoplasms are well differentiated and are difficult to distinguish from chondroma (conventional chondrosarcomas); some have mostly the appearance of primitive mesenchyma tissue (myxosarcoma-like) with abundant basophilic interstitial mucin and rare foci of chondroid differentiation (mesenchymal chondrosarcoma); other neoplasms are composed of highly anaplastic cells and have only a few areas in which differentiation into chondrocytes and chondroid matrix is apparent. Nonneoplastic bone can be present because of endochondral ossification of the malignant cartilage. Chondrosarcomas have a longer clinical course, grow more slowly, and develop metastases later than osteosarcomas. Metastases are usually to the lung by way of the venous system without metastasis to the regional or bronchial lymph nodes.

1087

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Osteomas are uncommon benign neoplasms that usually arise from bones of the head. They occur as a single, dense mass that projects from the surface of the bone (Fig. 16-72). They do not invade or destroy adjacent bone; their growth is slow and progressive but not necessarily continuous. Microscopically, osteomas are covered by periosteum and are composed of cancellous bone that becomes denser with time. Trabeculae are lined by well-differentiated osteoblasts and osteoclasts. The intertrabecular spaces contain delicate fibrous tissue, adipocytes, and hemopoietic tissue.

Osteosarcomas are malignant neoplasms in which neoplastic cells form bone, osteoid, or both. They can be classified as simple (bone formed in a collagenous matrix), compound (both bone and cartilage are present), or pleomorphic (anaplastic, with only small islands of osteoid present). Classification has also been based on cell type and activity (osteoblastic, chondroblastic, or fibroblastic), radiographic appearance (lytic, sclerotic, or mixed), or origin (central, juxtacortical, or periosteal). An uncommon form of osteosarcoma is the telangiectatic type that grossly resembles hemangiosarcoma. Microscopically, telangiectatic osteosarcomas are composed of osteoblasts, osteoid, and large cystic, blood-filled cavities lined by malignant osteoblasts. Osteosarcomas are common neoplasms, comprising approximately 80% of all the primary bone neoplasms in the dog. They arise most commonly in the metaphyses (distal radius, distal tibia, and proximal humerus are the most usual sites) (Fig. 16-73). However, osteosarcomas can occur in ribs, vertebrae, bones of the head, and various other parts of the skeleton (Fig. 16-74). Rarely, they arise in soft tissue (extraskelatal osteosarcoma). Typically, these neoplasms occur in mature dogs of the large and giant breeds. Growth of the neoplasm is often rapid and painful. Grossly, central or intraosseous osteosarcomas have a gray-white appearance and contain variable amounts of mineralized bone. Large, pale areas surrounded by zones of hemorrhage (areas of infarction) and irregular areas of hemorrhage are common in rapidly growing intramedullary neoplasms. Neoplastic tissue tends to fill the medullary cavity locally and can extend proximally and distally, but typically does not penetrate articular cartilage. Therefore osteosarcomas do not invade into the joint space. Cortical bone is usually destroyed, and neoplastic cells penetrate and undermine the periosteum and can extend outwardly as an irregular lobulated mass. Destruction of cortical bone is accompanied by varying amounts of reactive (nonneoplastic) periosteal bone. Microscopically, variable amounts of woven bone or osteoid are produced by the neoplastic osteoblasts (Fig. 16-75). Bone formation by the malignant cells can be abundant and widespread, or it can be minimal, as in anaplastic or fibroblastic osteosarcomas that are composed of sheets of poorly differentiated mesenchymal cells or fibroblastic tissue. Distinguishing between an intramedullary fibrosarcoma, and fibroblastic osteosarcoma can be difficult to impossible, especially in small biopsy samples. It was hoped that immunostaining for the osteoblast-specific protein osteocalcin might be useful in this regard, but it has been reported in human medicine that fibroblastic osteosarcomas commonly no longer express osteocalcin so the applied value of this technique can be low. In terms of biologic behavior, osteosarcomas in the dog are characterized by aggressive local invasion and, except for those arising in the axial skeleton and particularly the head, early hematogenous pulmonary metastasis. Although pulmonary metastasis is common and occurs early, metastasis can be widespread and can involve both soft tissue and other bones.

Fig. 16-72 **Osteoma, bone, maxilla and maxillary sinus, sheep.** The osteoma has proliferated and formed a dome-shaped mass above the normal contour of the maxilla and has compressed the maxillary sinus. This mass was hard throughout and composed of closely spaced trabeculae lined by well-differentiated osteoblasts. An *Oestrus ovis* larva is present in the nasal cavity. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-73 Osteosarcoma, bone, distal radius, dog.** Osteosarcoma has lysed and replaced normal bone. There is reactive periosteal bone formation (*arrowheads*) and a large area of hemorrhage and necrosis (\*). (Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

The previous description relates to central or intraosseous osteosarcomas. Periosteal osteosarcomas also have an aggressive behavior and invade into the medullary cavity from the periphery. As with central or intraosseous osteosarcomas, periosteal osteosarcomas cause bone lysis and reactive bone formation in addition to production of neoplastic bone. At the time of presentation, often it is not possible to determine if the osteosarcoma originated from the periosteum or the medullary cavity. Rarely, osteosarcomas are also juxtacortical (parosteal) in origin. These neoplasms arise within the periosteum and form an expansive mass that adheres to and surrounds, but does not invade, the underlying cortex. Invasion of the shaft and metastasis can occur with parosteal osteosarcomas but is a late event, so early en bloc excision might effect a cure.

## Pathologic Basis of Veterinary Disease, 4th Edition

Although parosteal osteosarcomas are very rare, it is important to distinguish them from periosteal osteosarcomas because parosteal osteosarcomas have a more favorable prognosis.

Fig. 16-74 **Osteosarcoma, bone, wing of ilium, dog.** Although the mass appears to be growing mostly by expansion into the adjacent soft tissues, it has invaded and lysed the underlying ilium and is focally invading the lumbar vertebra. Sagartz, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Multiple skeletal osteosarcomas that occur in human beings and dogs could represent a primary neoplasm that has metastasized to bone. The lesions have a random distribution, and pulmonary metastases are likely to be present. Alternatively, multiple skeletal osteosarcomas could have a multicentric origin. Metastasis of skeletal osteosarcoma to other bones in the dog has been reported to be higher in dogs receiving chemotherapy.

Although the cause of naturally occurring osteosarcomas in human beings and domestic animals is largely unknown, osteosarcomas can develop in association with other diseases. Osteosarcomas have been associated with bone infarctions, previous fractures, and the use of metallic fixation devices in human beings and domestic animals. Osteosarcomas of viral origin are reported in mice.

A unique form of skeletal malignancy occurs in the skull of the dog and is awkwardly called a multilobular tumor of bone (older literature calls this chondroma rodens). These are single, nodular, smooth-contoured, immovable masses on the flat bones of the skull (bones of membranous origin) and the hard palate. Neoplastic tissue is firm and the cut surface is composed of multiple, gray, partially mineralized lobules set in a background of fibrous tissue. These neoplasms are slow growing, are locally invasive, and can compress and invade the brain. They metastasize to the lungs late in the clinical course, and the metastases are frequently small and clinically silent. The microscopic appearance consists of multiple lobules, each having centrally located cartilage or bone surrounded by plump mesenchymal cells that blend into well-differentiated interlobular fibrous tissue.

1090

1091

Various other neoplasms such as liposarcomas, giant cell tumors, and hemangiosarcomas can arise in bone, and neoplasms such as lymphosarcomas and plasma cell myeloma can involve the bone marrow and surrounding bone.

### 16.2.8 SECONDARY NEOPLASMS OF BONE

At autopsy, 60% of (human) cancer patients have skeletal metastases. These are predominantly in red bone marrow, where the vascular sinusoidal system is apparently predisposed to trap circulating malignant cells. The true incidence of skeletal metastasis in animals is unknown and might be low because early euthanasia shortens the course of the disease. However, bone scanning techniques and detailed necropsies might establish that skeletal metastases are more common than presently estimated. Metastatic neoplasms in bone can be associated with pain, hypercalcemia, lysis of bone, pathologic fracture, and reactive new bone formation. Rib shafts, vertebral bodies, and humeral and femoral metaphyses (proximal appendicular skeleton) are common sites of metastatic neoplasms in dogs. In about 50% of the carcinomas present in the proximal appendicular skeleton in the dog, there is no clinical evidence of a primary carcinoma, and at postmortem, a primary carcinoma is not found. Consideration should be given to these being primary intraosseous carcinomas. In cats, skeletal metastases are rare, but the distal appendicular skeleton appears to be the predisposed sites. In cats, clinically silent pulmonary carcinomas can have a history of sloughing of multiple claws. Histopathologic examination of an amputated affected digit reveals metastatic pulmonary carcinoma with involvement mostly in the third phalanx causing destruction of the nail bed epithelium and sloughing of the claw.

### 16.2.9 FRACTURE REPAIR

Broken bones are a common occurrence. It is important to understand how and why fractures heal, and more importantly why they do not. Fractures can be classified as traumatic (normal bone broken by excessive force) or pathologic (an abnormal bone broken by minimal trauma or by normal weight bearing). Osteomalacia,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

osteomyelitis, and bone neoplasms are examples of lesions that can weaken a bone and predispose it to pathologic fracture. Microcracks might predispose to development of fracture with less than expected trauma, but to date this has not been proven.

**Growth plate:** The Salter-Harris classification of growth plate fractures has been widely accepted and can be readily found in texts on clinical orthopedics. Growth plate fractures that involve only the hypertrophied layers of cartilage and/or the primary trabeculae (Salter-Harris I and II) usually heal with few or any complications. Fractures which cross the growth plate (III and IV) or crush the plate (V and VI) have the potential to heal with secondary growth deformities. Fractures that crush or cross the growth plate could irreversibly injure chondrocytes of the reserve (resting) cell layer of the growth plate or damage the branch of the epiphyseal artery that nourishes these cells. Loss of reserve cells can result in premature closure of the growth plate in these regions.

**Trabecular bone:** Fractures of trabeculae without external deformation of the cortex are called infractions. These are often associated with inflammation or necrosis of bone as predisposing factors.

**Cortical bone:** Fractures of cortical bone can be classified in many other ways: closed or simple, if the skin is unbroken; open or compound, if the skin is broken and the bone is exposed to the external environment; comminuted, if the bone has been shattered into several small fragments; avulsed, if the fracture was caused by the pull of a ligament at its insertion into bone; greenstick, if one side of the bone is broken and the other side is only bent so that there is no separation or displacement; and transverse or spiral, depending on the orientation of the fracture line.

*Stable fracture repair* means that the fracture ends have been immobilized to give relative clinical stability (not necessarily weight-bearing ability), but have not been rigidly fixed by surgery (Table 16-6). The events that normally occur in the healing of a closed stable fracture of cortical bone are summarized later (Fig. 16-76). The reader should understand that this description represents a summary of a complex process that is subject to a great deal of variation. At the time of fracture, the periosteum is torn, the fragments are displaced, soft tissue is traumatized, and bleeding occurs forming a hematoma. Because of impaired blood flow and isolated bone fragments, bone at the broken ends and marrow tissue can undergo necrosis. The hematoma and tissue necrosis can be important in subsequent callus formation. Growth factors are released by macrophages and platelets in the blood clot and the proliferating osteogenic tissue, and even from the dead bone by the lysis and acidification of the matrix. These growth factors (bone morphogenetic proteins, TGF- $\beta$ , and platelet-derived growth factors among others) are important in stimulating proliferation of repair tissue (woven bone). Undifferentiated mesenchymal cells having osteogenic potential and reactive vascular proliferation begin to penetrate the hematoma from the periphery in 24 to 48 hours. The mesenchymal cells are derived from the periosteum, endosteum, stem cells in the medullary cavity, and possibly from metaplasia of endothelial cells. These mesenchymal cells proliferate in the hematoma to form a loose collagenous tissue. This proliferation of collagen-producing mesenchymal cells and neovascularization has been called “granulation tissue.” This is misleading because granulation tissue is committed to becoming fibrous tissue, whereas the mesenchymal cells in the early stages of fracture healing have the potential to undergo metaplasia to cartilage and bone. Woven bone is visible microscopically as early as 36 hours and regenerating nerve fibers are visible in the hematoma as early as 3 days.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 16-6 Stable Fracture Repair

Time	Tissue at Repair Site	Stability
Immediate	Hematoma	Unstable
24-48 hr	Undifferentiated mesenchymal cells and neovascularization	Unstable
36 hr	Earliest woven bone	Unstable
4-6 wk	Primary callus of woven bone and possibly hyaline cartilage	Stable
Months to years	Modeling of woven bone into lamellar bone	Stable

Fig. 16-76 Schematic diagram of the temporal course of callus formation and fracture repair. (Redrawn from Rubin E: Essential pathology, ed 3, Baltimore, 2001, Lippincott Williams & Wilkins.)

The term “callus” refers to an unorganized meshwork of woven bone that forms after a fracture. It can be external (that formed by the periosteum) or internal (that formed between the ends of the fragments and in the medullary cavity or endosteum). This “primary” callus should bridge the gap, encircle the fracture site, and stabilize the area (Fig. 16-77). In time, woven bone at the fracture site is replaced by stronger, mature lamellar bone (secondary callus). Depending on the mechanical forces acting at the site, the callus can eventually be reduced in size by osteoclasts until the normal shape of the bone is restored. This process, however, might take years to complete.

Callus can contain hyaline cartilage. The amount of cartilage present in the callus reflects the adequacy of the blood supply. Less than optimal oxygen supply promotes mesenchymal stem cells to differentiate into chondroblasts rather than osteoblasts. Cartilage does not provide as strong a callus as woven bone. However, it will eventually undergo endochondral ossification and therefore ultimately contribute to the formation of the bony callus.

Rigid fracture repair is usually due to surgical intervention and application of devices to keep the bone ends in contact or in very close proximity and keep the fracture stable during the repair process. Ideally (but rarely achieved across an entire fracture) contact healing occurs. This is when the fractured ends are touching each other and there is no instability. In such conditions, healing is by direct osteonal bridging of the fracture site (Fig. 16-78). Osteoclasts forming channels for new osteons will “jump” the fracture line and the new osteons will “knit” the bone ends together without formation of a callus. If there is a gap present between the bone

1092

1093

## Pathologic Basis of Veterinary Disease, 4th Edition

ends but it is less than 1 mm, bone cells will migrate from the fracture ends and form lamellar bone at a right angle to the fracture line (Fig. 16-79). This will eventually model into osteonal bone parallel to the long axis of the bone. In rigid fractures with gaps greater than 1 mm, woven bone fills the gap and must be modeled into osteonal bone.

**Fig. 16-77 Fractures, stable and unstable, bone, rib. A, Unstable fracture.** The fractured edges of the rib are improperly aligned, and there is abundant external callus composed of both cartilage and bone (*arrows*) and fibrous tissue mixed with hemorrhage. Fibrous tissue is produced in regions of tension in an unstable fracture. **B, Stable fracture.** The fractured edges of the rib are adequately aligned, and the fracture is stabilized by abundant cartilaginous callus that is being replaced by new bone. Note the location of the original cortex (*arrow indicates original periosteal surface*). (*A, Courtesy College of Veterinary Medicine, University of Illinois. B, Courtesy Dr. F. A. Leighton, College of Veterinary Medicine, University of Saskatchewan; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The most common complications of fracture healing are inadequate blood supply, instability, and infection. If the blood supply is less than optimal, then hyaline cartilage will form as described previously. If blood supply is disrupted to the point of anoxia, necrosis will occur. Mechanical tension and compression at the fracture site influence the reparative process. Excessive movement and tension favor the development of fibrous tissue. Mature fibrous tissue is not wanted in the callus because it does not stabilize the fracture and, unlike cartilage, will not act as a template for bone formation. Excessive fibrous tissue between bone ends in a fracture might result in a nonunion. With time, the bony ends of the nonunion can become smooth and move in a pocket of fibrous tissue and cartilage to form a false joint or pseudoarthrosis. Other factors that can interfere with the normal repair process include malnutrition, bacterial osteomyelitis, and the interposition of large fragments of necrotic bone, muscle, or other soft tissue that might lead to delayed union or nonunion. Fractures heal more slowly in aged animals likely because of decreased presence of red marrow and its stromal stem cells.

There are several complications of fracture repair specifically associated with metallic implants used in fracture stabilization. Metallic devices that are too large deprive the bone of normal mechanical forces (stress shielding) and result in bone loss (disuse atrophy). Intramedullary fixation devices have the potential to damage the blood supply. Implanted material (metal, plastics, and bone cement) often is separated from the surrounding bone by a thin layer of fibrous tissue, sometimes with metaplastic cartilage that forms in response to operative trauma, implant mobility, or corrosion of the implant. In addition, the implant surface can be a nidus for bacterial growth, and the admixture of bacteria with amorphous host fluid can form a biofilm that is resistant to antibiotics and host inflammatory cells. Microscopic particulate debris from implanted fixation materials (“wear debris”) can elicit a macrophage or multinucleated giant cell response. These inflammatory cells can release cytokines and growth factors that result in bone resorption and deterioration at the bone-implant surface, causing loosening and failure of the implant. Neoplasia thought to be induced by metallic fracture fixation devices has been reported rarely in the veterinary literature and is usually secondary to chronic osteomyelitis. The mechanism by which chronic osteomyelitis could be a predisposing factor for development of osteosarcoma is not known for certain. Generally, it is believed that any lesion that causes cell proliferation (as would be expected in chronic osteomyelitis) can increase the chance of cancer-causing spontaneous DNA damage by such things as free radicals and solar radiation. Pulmonary embolization of marrow fat from the trauma of the fracture or from trauma associated with repair of the fracture can cause severe clinical disease in human beings. It appears that the frequency of fat embolization secondary to trauma to the bone marrow is relatively common in human beings and dogs, but that clinical consequences of such embolization are relatively rare. Experimentally, fat embolization can be created readily in dogs by the reaming of the medullary cavity followed by pressurization. Interestingly, fat released from the marrow cavity in dogs by reaming is greater from intact bones than from fractured bones, presumably caused by decompression of the marrow cavity by the fracture in the latter. About 1% of human beings with hip replacement surgery can develop acute right-sided congestive heart failure because of embolization of fat from the surgery site to the lung.

### 16.3 DISEASES OF THE JOINTS

The joints or junctions between the bones can be classified as those that provide for little movement (fibrous joints or synarthrosis [e.g., sutures between the bones of the skull]) or limited movement (cartilaginous joint or amphiarthrosis [e.g., intervertebral joints]) and those that facilitate motion (synovial joint or diarthrosis [e.g., stifle joint]). The postmortem examination and evaluation of the joints is presented in [Appendix 16-1](#).

#### 16.3.1 ABNORMALITIES OF GROWTH AND DEVELOPMENT

##### 16.3.1.1 ARTHROGRYPOSIS

*Arthrogryposis* refers to the congenital contracture of a joint. Usually this is bilateral and symmetric. The cause of arthrogryposis is often not established when it occurs sporadically. However, the pathogenesis is well established in outbreaks involving damage to the fetal central nervous system with intrauterine viral infections (Akabane virus and bluetongue virus) in cattle and sheep or ingestion of poisonous plants by the dam (lupine poisoning in cattle and poison hemlock in pigs). In some cases, the central nervous system lesions are clearly hereditary, with significant numbers of offspring affected after introduction of a new sire. The central nervous system lesions result in degeneration or atrophy of muscle groups with subsequent contraction of the distal limb. Alternatively, maternal intoxication with certain alkaloids (coniine in poison hemlock) and lupine plants (anagyrine) is believed to cause sustained contraction of uterine muscle. It is suspected that such uterine tension causes flexion of the distal limbs and eventually atrophy of the flexure muscles. In all of these situations, there is no primary problem in the joint. Usually upon sectioning the tendons or the articular capsule these contractures can be relieved and the joint straightened. In rare circumstances, there is congenital articular malformation resulting in incongruous joint surfaces.

1094

1095

**Articular cartilage:** Articular cartilage is usually normal, but subtle malformations can be present.

**Articular capsule, synovium, synovial fluid:** Articular capsule/synovium/synovial fluid is without gross lesions other than the lack of flexibility.

**Subchondral bone:** Subchondral bone is usually normal other than subtle malformation.

##### 16.3.1.2 HIP DYSPLASIA

Hip dysplasia of the dog is a major orthopedic problem and is most common in large and giant breeds. Many different theories regarding the etiopathogenesis have been advanced, but most agree that it is a biomechanical disease in which joint laxity of the hip (instability) is one of the essential early findings, eventually resulting in chronic subluxation and severe secondary degenerative joint disease with marked remodeling of the acetabulum and femoral head and neck. Heredity clearly plays a role, and by selective breeding the prevalence of the disease has been significantly reduced. The lesions are not present at birth but can be well advanced by 1 year of age. Weight and overexercise also might contribute to the time of onset of signs and severity of the disease. Dogs on restricted calorie intake have significantly delayed time of onset of both hip dysplasia and degenerative joint disease.

Hip dysplasia, which might be inherited, also occurs in bulls of some beef breeds. Affected animals have shallow acetabula, joint laxity, and instability, which lead to degenerative joint disease early in life.

## Pathologic Basis of Veterinary Disease, 4th Edition

Articular cartilage: In the advanced disease, there is notable erosion and ulceration of articular cartilage of both the femoral head and acetabulum.

Articular capsule/synovium/synovial fluid: In advanced disease, the articular capsule is stretched and thickened, and areas of osseous and cartilaginous metaplasia can develop within it. The round ligament of the femoral head can be ruptured. It has been reported that the earliest detectable microscopic lesion in hip dysplasia is a mild lymphoplasmacytic synovitis (see previous discussion in reactions to injury). Although this is likely secondary to undetectable early cartilage breakdown, it is intriguing that this inflammation is the first observable microscopic lesion in any structure of the joint in hip dysplasia.

Subchondral bone: In advanced disease, the dorsal rim of the acetabulum flattens and becomes shallow and wide. Subsequent to ulceration of cartilage of the femoral head there is eburnation of underlying bone and formation of periarticular osteophytes on the femoral neck and acetabulum (Fig. 16-23).

### 16.3.2 INFLAMMATORY LESIONS

The term *arthritis* implies lesions present in articular cartilage in addition to inflammation of the synovial membrane, whereas the term *synovitis* is restricted to inflammation of the synovium (Table 16-3). Arthritis is characterized by the presence of inflammatory cells in the synovial membrane, but the nature of the inflammatory process is often reflected best in the volume and character of the exudate in the joint fluid. It is useful to classify joint diseases as inflammatory or noninflammatory. The problem with this classification becomes apparent when striking lymphoplasmacytic and histiocytic synovitis is found in “noninflammatory” diseases, such as hip dysplasia and degenerative joint disease. Arthritis can be classified by cause (bacterial, viral, sterile immune-mediated, or urate deposits of gout), duration (acute, subacute, or chronic), or the nature of the exudate produced (serous, fibrinous, purulent, or lymphoplasmacytic). The term “arthropathy” is all-encompassing and refers to any joint disease. Like osteomyelitis, arthritis can be a serious threat to the well-being of an animal. It is painful and can lead to permanent deformity and crippling. Chronicity can be due to an inability of the animal to remove the causative agent or substance, repeated trauma, persistence of bacterial cell wall material, or ongoing autoimmune-mediated inflammation. If there is irreversible damage to cartilage or synovium, even if the cause of the primary inflammation is cleared, the joint could progress to degenerative joint disease. Injury to intraarticular structure can be due to the offending agent or substance, to the inflammatory process, to proteolytic enzymes released from cells of cartilage or synovial tissues, to activation of latent matrix metalloproteinases, or to failure of degenerating or necrotic chondrocytes to maintain the proteoglycan content of the matrix. Mediators of inflammation that contribute to joint injury include prostaglandins, cytokines, leukotrienes, lysosomal enzymes, free radicals, nitric oxide, neuropeptides, and products of the activated coagulation, kinin, complement, and fibrinolytic systems in synovial fluid.

1095

1096

### 16.3.2.1 INFECTIOUS ARTHRITIS

Neonatal bacteremia secondary to omphalitis or oral-intestinal entry commonly leads to polyarthritis in lambs, calves, piglets, and foals. Bacteria can also reach the joint by direct inoculation, as in a puncture wound, by direct extension from periarticular soft tissue, or by extension from adjacent bone. Bacterial osteomyelitis can extend through the cortex at the metaphysis (Fig. 16-45) (especially in young animals in which this cortex is not a completed wall of bone) into the joint, or epiphyseal osteomyelitis can lyse directly through articular cartilage (Fig. 16-46). Bacterial arthritis is not common in dogs or cats. In a retrospective study in a university veterinary hospital, most cases of bacterial arthritis in dogs involved the stifle and were complications from surgery on the stifle joint. Next most frequent in this series was

## Pathologic Basis of Veterinary Disease, 4th Edition

---

hematogenous arthritis, and in most of these dogs an underlying chronic degenerative arthritis was thought to be the predisposing factor. The mechanisms of this predisposition is uncertain but might be related to the increased blood flow.

Because the lesions of infectious arthritis can be very similar from different inciting agents, lesions will be presented first. Lesions are presented by time and whether the initial exudates is/was mostly neutrophilic (suppurative arthritis) or fibrinous (fibrinous arthritis) ([Table 16-3](#)).

**Articular cartilage:** The response of cartilage to inflammation with time will depend on the nature and severity of the exudates. In acute inflammation independent of the nature of the initial exudate, the articular cartilage is normal grossly and microscopically. In subacute suppurative or fibrinous arthritis, there can be thinning of the cartilage because of lysis and erosion (see previous discussion) of collagen by the enzymes in the exudates, activation of matrix metalloproteinases, and collapse of the cartilage as a result of a loss and failure to replace the water-binding proteoglycans by the degenerate or necrotic chondrocytes. In chronic suppurative arthritis, extensive cartilage erosion and ulceration is expected ([Fig. 16-80](#)). In chronic fibrinous arthritis, there can be cartilage ulceration as well, but it is not as consistent as with chronic suppurative arthritis. In addition, in chronic fibrinous arthritis, pannus formation can occur (pannus is unusual with chronic suppurative arthritis). As described previously, cartilage erosion and ulceration is expected subsequent to pannus formation. In chronic infectious arthritis in which there was no acute exudate into the joint, cartilage loss might be quite slow and be secondary to low grade lymphoplasmacytic synovitis (see later discussion).

**Articular capsule/synovium/synovial fluid:** In acute suppurative and fibrinous arthritis, the synovial fluid is usually reduced in viscosity because of a combination of enzymatic digestion of the glycosaminoglycans and dilution of the synovial fluid with edema. The fluid may be turbid because of the presence of neutrophils and strands of fibrin and possibly reddened because of presence of slight hemorrhage. Exudate in the synovial fluid can be extensive in acute lesions ([Fig. 16-81](#)), whereas the synovial membrane can appear only slightly hyperemic and edematous even microscopically. Therefore in acute arthritis, evaluation of synovial fluid is much more informative than evaluation of synovial membrane. Reports in the horse suggest that culturing for bacteria in synovial fluid is more sensitive than culturing synovial membrane or looking for bacteria in the synovial membrane with special stains histopathologically. In contrast, in the dog, culturing the synovial membrane has been reported to be more sensitive than the synovial fluid. In acute fibrinous or suppurative bacterial arthritis that has been treated effectively with antibiotics, the lesions can resolve without residual defects.

1096

1097

**Fig. 16-80 Chronic suppurative (active) arthritis, right tibial-tarsal bone, articular surface, hock, horse.** The suppurative inflammation has caused widespread erosions (lysis) of the articular cartilage that appear as darkened pitted areas on the articular surface (*left*). The cartilage erosion has allowed the red appearance (vascularization) of the underlying subchondral bone marrow to be seen. Normal left tibial-tarsal bone is on the right. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Fig. 16-81 Acute fibrinous arthritis, bone, tibial-tarsal joint (hock), calf.** The articular cavity is distended by layers of yellowish-brown fibrin that coat the synovial surface (*arrows*) of the joint capsule. (*Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.*)

In subacute suppurative and fibrinous arthritis and in subacute infectious arthritis in which there was no acute exudate into the joint, independent of cause, the synovium is expected to have lymphoplasmacytic inflammation and variable hyperplasia of synovial lining cells (Fig. 16-82). The lymphoplasmacytic inflammation reflects the immunogenicity of the infectious agent. The synovial hyperplasia is a nonspecific response but presumably is an attempt at increasing production of synovial fluid. In subacute (and chronic) suppurative and fibrinous arthritis, it is uncommon to find significant numbers of neutrophils and fibrin deposits, respectively, in the synovial membrane. Rather, the neutrophils and fibrin exude from the membrane and enter the joint space.

In chronic suppurative arthritis, granulation tissue with pronounced lymphoplasmacytic inflammation can replace the synovial membrane and there can be notable fibrosis of the articular capsule. In chronic fibrinous arthritis, if deposits of fibrin are extensive, they can be invaded and replaced by fibrous tissue, leading to restricted articular movement. Chronic fibrinous arthritis (e.g., erysipelas and mycoplasmosis [see later discussion]) of long duration is often accompanied by pronounced villous hypertrophy, lymphoplasmacytic synovial inflammation and pannus formation, and progressive destruction of cartilage (Fig. 16-83). In both chronic fibrinous arthritis and chronic suppurative arthritis, fibrin and pus (suppurative exudate) continue to be produced and are present in the joint space in active (bacteria is still present) lesions. Fibrous ankylosis of joints can occur in extreme cases of either fibrinous or suppurative arthritis.

**Subchondral bone:** Subchondral bone is affected only secondarily in infectious arthritis. In chronic purulent arthritis, the exudates can erode the articular cartilage and extend into the subchondral bone plate (Fig. 16-84). If there is severe chronic lameness, the subchondral bone can undergo disuse atrophy and appear osteopenic.

### 16.3.2.1.1

#### Bacterial Arthritis

Lesions of infectious arthritis based on the nature of the exudates and duration of the lesion were presented previously. The duration of bacterial arthritis is variable. Some organisms are rapidly removed and synovitis is short-lived. In other instances, bacteria can persist, and the inflammatory process can become chronic but still active. The extent and mechanism of cartilaginous destruction differ somewhat depending on the nature of the exudates. In turn, the nature of the exudates can depend on the infectious agent involved. Generally, fibrinous inflammation is expected more often with gram-negative bacteria, whereas suppurative arthritis is expected more often with gram-positive bacteria. The exudates in the joint in acute stages of infection with gram-positive bacteria, however, can be mostly fibrinous and become purulent with time. An example of chronic fibrinous arthritis is that caused in pigs by *Erysipelothrix rhusiopathiae* septicemia. This is an exception to the above generality about fibrinous inflammation being due to gram-negative bacteria. *Erysipelothrix rhusiopathiae*, a gram-positive bacteria, causes a fibrinous arthritis that does not become purulent with time. Survivors can have lesions secondary to localization of *Erysipelothrix rhusiopathiae* in the skin, synovial joints, valvular endocardium, or intervertebral disks. Chronic painful polyarthritis is a common sequela. *Arcanobacterium pyogenes* is a common cause of suppurative arthritis in cattle and pigs. Many different infectious agents cause arthritis in animals. For example, *Escherichia coli* (fibrinous) and streptococci (suppurative) initially cause septicemia in neonatal calves and piglets and then localize in joints, meninges, and, sometimes, serosal surfaces. Often synovitis is acutely serofibrinous and becomes more purulent with time. *Haemophilus parasuis* (fibrinous) causes Glasser's disease in pigs 8 to 16 weeks of age. Lesions consist of fibrinous polyserositis, polyarthritis, and meningitis. Acute serofibrinous polyarthritis is seen frequently in cattle dying of thrombotic meningoencephalitis caused by *Haemophilus somnus*.

Chronic marked suppurative discospondylitis (inflammation of the intervertebral disc and adjacent vertebrae) with marked lysis of the disk and cortices, epiphyses, and metaphyses of the adjacent vertebrae. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

*Borrelia burgdorferi*, a spirochete, is the tick-borne cause of Lyme disease (borreliosis). The arthritis in Lyme disease is seen in dogs, cattle, and horses. Single or multiple joints can be affected. In experimental studies in dogs, lameness developed in about half of the infected animals. Time of onset of the lameness was 2 or more months after infection. In the acute stages of the disease, the exudate is a combination of fibrinous and suppurative (fibrinopurulent) inflammation. In the chronic stages, pannus (usually a sequela to fibrinous arthritis) and chronic suppurative inflammation can be seen.

### 16.3.2.1.2

#### Mycoplasma Arthritis

Generally the nature of the lesions of mycoplasma arthritis are comparable to those described previously for bacteria causing fibrinous arthritis. Usually multiple joints are involved, indicating the hematogenous route of infection. In pigs, *Mycoplasma hyorhinis* and *Mycoplasma hyosynoviae* can be commonly isolated from nasal and pharyngeal regions in asymptomatic pigs. *Mycoplasma hyorhinis* causes fibrinous polyarthritis and polyserositis in weanling pigs. *Mycoplasma hyosynoviae* causes fibrinous polyarthritis in older pigs (more than 3 months old). It is not certain how these mycoplasma gain access to the circulation and ultimately the joints, but it is likely an oral-pharyngeal/pulmonary route secondary to stress or concurrent respiratory disease.

*Mycoplasma bovis* causes fibrinous to pyogranulomatous polyarthritis in feedlot cattle, and the disease is characterized by lameness and swelling of the large synovial joints of the limbs, which can contain large volumes of serofibrinous to frankly suppurative exudate. *Mycoplasma bovis* likely gains access to joints through the blood stream, possibly secondary to mycoplasma pneumonia or mastitis.

### 16.3.2.1.3 Viral Arthritis

The first viral arthritis discovered was the reoviral arthritis in chickens. At the time, there was great hope that idiopathic arthritides (such as rheumatoid arthritis) would also be shown to be viral. However, other than in goats, viral arthritis does not appear to be a significant or even recognized disease in domestic mammals. The caprine arthritis-encephalitis virus (a retrovirus) causes chronic fibrinous arthritis in older goats. The disease is characterized by debilitating lameness, carpal hygromas, and distention of the larger synovial joints. Peculiar to chronic cases of viral arthritis in goats due to caprine arthritis-encephalitis virus, necrosis and mineralization of synovial villi can give the membrane a chalky white appearance. Also present is lymphoplasmacytic synovitis, synovial villous hyperplasia, and pannus formation typical of chronic fibrinous arthritis.

### 16.3.2.2 NONINFECTIOUS ARTHRITIS

The causes of inflammatory conditions should be considered in two broad categories: infectious and noninfectious. The infectious causes of arthritis were presented previously. Here we consider specific joint diseases that have inflammation as the initiating event but are known to be sterile. Noninfectious arthritis is often classified as erosive or nonerosive depending on the effect of the disease on articular cartilage. Following are three types of sterile erosive arthritis.

1098

1099

#### 16.3.2.2.1 Rheumatoid Arthritis

Rheumatoid arthritis in the dog is an uncommon, chronic, sterile, erosive polyarthritis that resembles the disease in human beings. In human beings and dogs, the cause is unknown, although it is clear that the process is immune mediated (involves humoral and cell-mediated immunity). Antibodies (rheumatoid factor) of the immunoglobulin (Ig)G or IgM classes are produced in response to an unknown stimulus. Alterations in the steric configuration of IgG, persistent bacterial cell wall components that cross-react with normal proteoglycans, anticollagen antibodies, and defective suppressor T-lymphocyte activity are factors that may be involved. Neutrophils activated by ingestion of immune complexes release lysosomal enzymes, which sustain the inflammatory reaction and injure intraarticular structures. The pathogenesis of joint destruction in rheumatoid arthritis was described previously in reaction to injury of joints to inflammation. In addition to inflammatory mediators and their effects on synovium and cartilage, rheumatoid arthritis characteristically has exuberant pannus formation (Fig. 16-75). Fibroblasts in pannus can enzymatically degrade cartilage, and pannus can act as a physical barrier between the synovial fluid and the cartilage preventing nutrition of the chondrocytes. Antibodies against normal and altered collagen from articular cartilage are present in human cases of rheumatoid arthritis and might be important mediators of the ongoing joint inflammation and injury that occur in this disease. In dogs, rheumatoid arthritis is characterized by progressive lameness involving the peripheral joints of the limbs.

#### 16.3.2.2.2 Reactive Arthritis

Reactive arthritis is the name given to a sterile erosive oligoarthritis of uncertain pathogenesis. This condition is rarely reported in domestic animals and is presented here because it likely is underdiagnosed. It is a known problem in primate research colonies as an arthritis that develops subsequent to diarrheal disease. In the dog, the term *reactive arthritis* is being used for sterile nonerosive arthritis secondary to infectious disease elsewhere in the body (see later section titled Nonerosive

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Noninfectious Arthritis). This is at odds with the condition recognized in human beings and nonhuman primates. Reactive arthritis is defined clinically as sterile inflammation in joints that occurs subsequent to infectious inflammation in other organ systems—usually intestinal and urogenital in human beings; and usually caused by bacteria such as *Yersinia*, *Salmonella*, *Campylobacter*, and *Shigella*. Several hypotheses have been presented: cross-reactivity (molecular mimicry) between bacterial heat-shock proteins and articular glycosaminoglycans, inexplicable homing of sensitized gut lymphocytes to joints, and inexplicable localization of antigenic bacterial peptidoglycans in joints. These are not mutually exclusive.

16.3.2.2.3

### Postinfectious Sterile Arthritis

Postinfectious sterile arthritis is suspected to represent the immune reaction to antigenic breakdown products of bacterial cell walls that can remain sequestered in a joint after a confirmed bacterial infection within the joint.

Articular cartilage: Rheumatoid arthritis, reactive arthritis and postinfectious arthritis are all erosive, and in some cases, the ulceration can be extensive. Cartilage erosion is not expected until at least the subacute phases of the disease. These diseases can be very chronic, lasting for months because of difficulty in controlling the condition with medication.

Articular capsule/synovium/synovial fluid: Grossly the lesions in advanced cases consist of marked villous hypertrophy of the synovial membrane, pannus formation, formation of periarticular osteophytes, and, when severe, fibrous ankylosis of affected joints. In severe cases, pannus formation can result in a velvetlike layer overlying the subchondral bone. Microscopically the alterations in the joint are hyperplasia of synovial lining cells and infiltration of large numbers of plasma cells and lymphocytes into the synovium. Additionally, necrotic foci, fibrinous exudate, and infiltrating neutrophils can be present in the synovium. Large numbers of neutrophils are present in the synovial fluid.

Subchondral bone: With severe ulceration and pannus formation, rather than sclerosis of subchondral bone, there can be lysis of subchondral bone by the ongoing pannus.

16.3.2.2.4

### Nonerosive Noninfectious Arthritis

Nonerosive noninfectious arthritis has been best described in the dog. Most are idiopathic symmetric oligoarthritis, but they can be associated with concurrent sterile immune-mediated diseases such as steroid responsive meningitis/arteritis, neoplasia, and infectious inflammation in other organ systems (nonerosive reactive arthritis). Systemic lupus erythematosus (SLE) can be associated with nonerosive arthritis. SLE is a chronic nonerosive oligoarthritis that is recognized in dogs. These dogs can have, in addition, dermatitis, anemia, thrombocytopenia, polymyositis, and glomerulonephritis. It is thought that synoviotrophic immune complexes are the mediators of this inflammation. Why this does not result in articular destruction as in rheumatoid arthritis is not apparent.

Articular cartilage: Articular cartilage lesions are not expected in nonerosive arthritis even when it is chronic.

1099

Articular capsule/synovium/synovial fluid: In these diseases, villous hypertrophy can be minimal to marked with variable neutrophilic and lymphoplasmacytic synovitis. Pannus formation does not occur, and destruction of articular cartilage is not to be expected. The exudate in the synovial fluid in chronic nonerosive arthritis is neutrophilic.

1100

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Subchondral bone: Subchondral bone lesions are not expected in nonerosive arthritis.

In sterile inflammatory joint disease, a definitive diagnosis is not often possible. It should be remembered that response to antibiotics does not confirm that a process was a result of infectious agents. Antibiotics that reduce gram-positive bacteria in the intestine may allow coliform overgrowth and increased lipopolysaccharide production. Increased intestinal absorption of lipopolysaccharide is associated with decreased clinical signs in autoimmune arthritis, possibly by the immune system down-regulating or by establishing a more rigorous recognition of self.

16.3.2.2.5

### Crystal Deposition Disease

Crystal deposition disease is characterized by deposits of minerals such as urates, calcium phosphates, and calcium pyrophosphates in articular cartilage and/or the soft tissue of joints. Clinical disease due to crystal deposition is rare in domestic mammals. Crystal-induced synovitis with secondary degeneration of articular cartilage occurs in gout when urate crystals are deposited in and around joints. Gout occurs in species that do not have the enzyme uricase (human beings, birds, and reptiles). Deposits of urate, called tophi, incite an acute to chronic granulomatous inflammation and can appear grossly as white caseous material. Deposition of calcium and phosphorus in different forms (calcium pyrophosphate deposition disease, “pseudogout,” and calcium phosphate deposition disease) in the soft tissue of the synovium, articular capsule, and adjacent ligaments has been reported in young dogs. Underlying metabolic diseases are not recognized. Single or multiple joints can be involved. The variable bone and cartilage changes that can be present might be secondary. Perhaps the most common crystal deposition disease, but usually clinically silent, is intraarticular crystal deposition disease. This is usually due to calcium pyrophosphate deposition. In horses and dogs, this can be present in locations subject to increased mechanical use (scapulohumeral joint of racing dogs and metacarpal- and metatarsal-phalangeal joints of horses). The deposition is initiated around the chondrocytes and can be seen grossly as bright white foci. The significance of the deposition is uncertain, but it might play a role in the progression of degenerative joint disease.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 16-7 Degenerative Joint Disease

Name of Stage	Gross Appearance	Microscopic Lesion
Chondromalacia	Softened	Decreased proteoglycan content apparent with histochemical stains for mesenchymal mucins
Erosion	Ranges from matted appearance and normal thickness to grossly apparent thinning	Loss of cartilage layers—ranges from earliest loss only of the surface layer to later stages of loss extending to tangential, radial, and eventually deep (mineralized layer)
Fibrillation	Frayed appearance	Condensation of collagen fibers (because of loss of water at this stage) and splitting of the matrix along the vertical axis of the collagen fibers (perpendicular to the joint surface)
Ulceration/eburnation of subchondral bone	Exposure of the subchondral bone; the bone surface can be polished very smooth by wear	Loss of cartilage to the level of the subchondral bone; vascular and marrow spaces of the bone become smaller as they fill with bone (osteosclerosis) because of increased mechanical use; the surface of the exposed bone can be smooth; this combination of increased density (osteosclerosis) and surface smoothness is termed eburnation

### 16.3.3 DEGENERATIVE JOINT DISEASE

Degenerative joint disease (osteoarthritis, osteoarthritis), recognized since antiquity, is a destructive disease of articular cartilage of synovial joints that occurs in all animals with a bony skeleton (Table 16-7). It can be monoarticular or polyarticular, can occur in immature or mature animals, and can be symptomatic or clinically silent. Affected animals have variable degrees of joint enlargement and deformity, pain, and articular malfunction. The etiopathogenesis of degenerative joint disease is incompletely understood, and it is likely that the term encompasses a variety of diseases that have a common end stage. Initial changes can be due to traumatic injury to articular cartilage, inflammation of the synovium, increased stiffness of the subchondral bone, or abnormalities in conformation, joint stability, and congruence of joint surfaces (Fig. 16-85). In addition, age-related degeneration of articular cartilage is common in all species but often is clinically insignificant. Lesions are of greatest importance when they occur at an early age and progress rapidly.

1100

1101

The initial biochemical change in articular cartilage in degenerative joint disease is loss of proteoglycan aggregates. In the early stages of degeneration, this loss of proteoglycans is associated with an increase in water content in the cartilage matrix. This early increase in the water content of the cartilage matrix in early stages of degenerative joint disease, coinciding with a decrease in cartilage matrix proteoglycans, seems contradictory because in normal cartilage, proteoglycans play a critical role in binding water. The explanation for this is not clear, but the increased water in the matrix is not bound normally to the proteoglycans and does not contribute to the normal lubrication and flushing of nutrients and waste products as described previously. Core proteins of proteoglycan aggregates are susceptible to the action of neutral proteoglycanases, which are increased in early degenerative joint disease. In electron micrographs, the findings include focal loss of the amorphous layer covering the surface of the articular cartilage and fraying of the superficial collagen fibers. Continued proteoglycan loss interferes with joint lubrication and allows collagen fibers to collapse on each

## Pathologic Basis of Veterinary Disease, 4th Edition

other along lines perpendicular to the joint surface because of the loss of the hydrated gel of proteoglycans and water that kept the fibers separated.

Fig. 16-85 Schematic diagram illustrating degenerative joint disease of the coxofemoral joint. (From Damjanov I, Linder J: Anderson's pathology, ed 10, vol 2, St Louis, 1996, Mosby.)

Synovitis in degenerative joint disease is secondary to release of inflammatory mediators by injured chondrocytes and from synovial macrophages that have phagocytosed cartilaginous breakdown products.

Articular cartilage: Lesions can be focal to diffuse within a joint. The loss of proteoglycans and improper binding of water (actual increase in water content) causes the articular cartilage to become soft (chondromalacia). In hinge-type joints, linear grooves can often be seen particularly in horses (Fig. 16-67, A). Histologically, these grooves are not erosions or ulcers but have all layers intact. They represent linear depressions in the cartilage associated with scattered necrotic chondrocytes and localized loss of proteoglycan. It is presumed that these depressions represent areas of collapse of the collagen fibers because of loss of proteoglycans and water. The pathogenesis of these grooves is uncertain, but they might represent sequelae to jetties of synovial fluid secondary to incongruities of the joint surfaces. Chondromalacia is followed by abnormal wearing of the cartilage and loss of very superficial layers (early erosion) resulting grossly in a matted appearance. As the lesions progress, erosions become deeper (cartilage is thinner) and grossly apparent fraying of collagen fibers along their radial arrangement can be seen (fibrillation) (Figs. 16-70, 16-71, and 16-72). Fibrillated cartilage can be yellow to brown. Advanced lesions can have notable loss of cartilage down to the mineralized layer and subchondral bone (ulceration) (Fig. 16-73).

Articular capsule/synovium/synovial fluid: Synovitis characterized by villous hypertrophy, hyperplasia of synoviocytes, and infiltration of lymphocytes, plasma cells, and macrophages is usually present in chronic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cases (Fig. 16-74). The synovial fluid does not have exudates and is clear and colorless but might have reduced viscosity because of increased plasma filtrate relative to glycosaminoglycans in the synovial fluid, and increased degradation of glycosaminoglycans by enzymes released by the inflamed synovium. Fibrosis of the articular capsule because of instability or release of cytokines such as TGF- $\beta$  might contribute, along with osteophytosis and joint incongruity, to the joint stiffness and limited range of motion seen in advanced degenerative joint disease.

**Subchondral bone:** Degenerative joint disease often progresses to sclerosis of subchondral bone, but some investigators consider stiffness (sclerosis) of subchondral bone to be the initial lesion and that this stiffness predisposes the cartilage to mechanical damage. If there is ulceration of cartilage and the joint is still used, the exposed bone can be polished smooth by wear (eburnation). Marginal (periarticular) osteophytes form and there can be pronounced modeling of the epiphyseal and metaphyseal bone because of altered mechanical use (Fig. 16-78). The joint might fuse because of combination of bony or fibrous bridging (ankylosis) of the joint space (Fig. 16-86). Subchondral bone cysts in degenerative joint disease are cavities in the subchondral bone with a synovial-like lining and peripheral osteoclastic bone lysis and fibrosis. Presumably, they arise secondary to fissures in the overlying cartilage or eburnated bone, allowing synovial fluid to be forced into the subchondral bone. These appear to be more common in human beings than domestic animals, and this might reflect the longer duration of the lesions in human beings. The Hartley guinea pig spontaneously develops degenerative joint disease in the stifles before 1 year of age. Subchondral cysts are present in the proximal tibial articular surface, and in this model they appear to be invaginations of synovial membranes surrounding the cruciate ligaments as they insert into the subchondral bone.

### 16.3.4 DEGENERATION OF INTERVERTEBRAL DISKS

Degeneration of the intervertebral disks is often an age-related phenomenon in many species. In general, loss of water and proteoglycans, reduced cellularity, and an increase in collagen content of the nucleus pulposus occur, so that the distinction between the nucleus pulposus and the annulus fibrosus is obscured. The central part of the disk is yellow-brown and is composed of friable fibrocartilaginous material (Fig. 16-87). These degenerative changes are likely caused by various metabolic and mechanical insults that lead to a breakdown of proteoglycan aggregates in the nucleus pulposus and to degenerative changes in the annulus fibrosus. Both rotational and compressive types of movement injure the annulus fibrosus. Changes in structure of the nucleus pulposus, together with a weakened annulus, often lead to concentric and radial tears or fissures in the annulus that allow bulging or herniation of the nucleus pulposus material (Fig. 16-88). Herniation is usually dorsal in domestic animals. In human beings (rarely in domestic animals), disk material can be extruded through the end plate into the vertebral body, producing a lesion known as Schmorl's node.

1102

1103

**Fig. 16-86 Ankylosing spondylosis, joints, intervertebral, bull.** Periosteal new bone formation on the ventral and lateral periosteal surfaces (not visible in this plane of section) of the vertebrae is called spondylosis and can be a result of mechanical instability or excess mechanical stress on the intervertebral discs (joints). The bony proliferation (ventrally) has bridged the joint space between the adjacent vertebrae and caused fusion (ankylosis) or ankylosing spondylosis. (Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.)

**Fig. 16-87 Intervertebral disc disease, degenerate intervertebral disc, prolapsed disc, ankylosing spondylosis, intervertebral joint, dog.** Dorsal protrusion of a degenerate nucleus pulposus has compressed the spinal cord. Marked ventral ankylosis (coalescing periarticular osteophyte formation) is secondary to the instability of the joint. (Courtesy J. King, College of Veterinary Medicine, Cornell University.)

**Fig. 16-88 Schematic diagram illustrating stages of prolapse of the nucleus pulposus in intervertebral disc disease. A, Prolapse of the nucleus pulposus may be secondary to partial rupture of the annulus fibrosus. B, Complete rupture of the annulus fibrosus allows extrusion of the nucleus pulposus into the vertebral canal.**

In chondrodystrophic breeds of dogs, such as the dachshund, chondroid metaplasia of the nucleus pulposus is followed by calcification during the first year of life. These alterations can result in disk prolapse, with total rupture of the annulus fibrosus and extrusion of disk material into the vertebral canal at sites of mechanical stress, such as the cervical and thoracolumbar vertebrae.

Senile degenerative disk disease is independent of breed in the dog and also occurs in human beings, pigs, and horses. These lesions are characterized by progressive dehydration and collagenization of the nucleus pulposus and degeneration of the annulus fibrosus. The lesions develop slowly, and calcification is rare. Prolapse of the disk is secondary to partial rupture of the annulus fibrosus and is characterized by bulging of the dorsal surface of the disk into the vertebral canal. An important consequence of degeneration of intervertebral disks is prolapse of the disk. Prolapse or herniation can be dorsal (spinal cord compression) or lateral (spinal nerve

## Pathologic Basis of Veterinary Disease, 4th Edition

---

compression and entrapment). Because each intervertebral joint is a three-joint complex (intervertebral joint and two facet joints), the reduced disk thickness that follows degeneration and dehydration allows overriding of articular facets and some degree of joint instability. These changes contribute to the evolution of degenerative disease and enlargement of articular facets. Enlargement of the facets can cause impingement on spinal nerves and even compression of the spinal canal because the medial aspect of these facets is adjacent to the intervertebral foramen. Degeneration of intervertebral disks and the ensuing intervertebral joint instability can result in the development of osteophytes on the ends of the vertebral bodies around or adjacent to the disk (spondylosis) in many species, such as dogs, cattle, pigs, and horses. Vertebral osteophytes are usually ventral and lateral; if dorsal, they can cause stenosis of the vertebral canal.

### 16.3.5 NEOPLASMS OF JOINTS

Essentially only malignant tumors are recognized as primary neoplasms within joints, and these arise from the synovial membrane but vary notably in their metastatic potential. These tumors are uncommon in dogs and very rare in other species. Articular cartilage, likely because of the limited ability of chondrocytes to divide, is not known to give rise to neoplasms. Two different malignancies of the synovium are recognized. One is derived from histiocytic cells and is called a histiocytic sarcoma. If the histiocytic malignancy is multicentric (present at multiple sites) the term *malignant histiocytosis* is used. If present as a single focus, it is called a histiocytic sarcoma. When presenting at multiple sites, it cannot be determined if this is a histiocytic sarcoma with metastasis or a truly multicentric malignant histiocytosis. As the name implies, these cells have a histiocytic phenotype; atypia is sometimes extreme with bizarre mitotic figures and pronounced pleomorphism. Histiocytic sarcomas have a high chance of distant metastasis.

Synovial cell sarcoma is the term given to a malignancy of synovial fibrocyte origin (Fig. 16-89). These are more common in joints, but synovia of tendon sheaths can be involved. These malignant cells are negative for histiocytic cell markers, positive for mesenchymal markers (vimentin), and inexplicably, a small percent of the malignant cells with a fibrocytic phenotype are positive for epithelial markers (cytokeratins). Such epithelial cell expression is not found in the synovia of normal joints. In human beings, there is a characteristic gene translocation that occurs in synovial cell sarcomas. Synovial cell sarcomas have a moderate to low chance of distant metastasis. Some fibrocytic cell tumors in the synovium have notable myxomatous metaplasia and have been called myxomas and benign because of the absence of distant metastasis. However, because of their ability to invade bone, these should also be considered low-grade malignancies. The lesions described later are for the fibrocytic synovial cell sarcoma and not histiocytic sarcoma.

1103

1104

**Fig. 16-89 Synovial cell sarcoma, joint, elbow, dog.** Synovial cell sarcoma presenting as a tan and hemorrhagic mass (*left*) within the joint has invaded into the distal humeral condyle (*arrow*) and caused pronounced lysis of the proximal ulna. (*Courtesy Dr. S.E. Weisbrode, College of Veterinary Medicine, The Ohio State University.*)

**Articular cartilage:** Articular cartilage is usually not affected other than secondarily as a result of a loss of subchondral bone support by the invading malignancy.

**Articular capsule/synovium/synovial fluid:** Synovium can be markedly and asymmetrically thickened with a gray to tan mass that has variable hemorrhage. The masses can be firm to gelatinous because of myxoid matrix produced by the neoplastic cells. Usually the mass is relatively confined to the region of the joint. Microscopically the mass has the appearance of a moderate- to low-grade fibrosarcoma, with little collagen production. Myxomatous metaplasia of the malignant cells can be seen in some cases giving the tumor a myxosarcoma appearance.

**Subchondral bone:** Radiographically, there is evidence of invasion into bone, usually on both sides of the joint space. However, this bone invasion can be subtle and often not apparent on gross examination. Subchondral and periosteal bone lysis can range from minimal to extensive but characteristically is present on both sides of the joint space. Sometimes it can be seen that the malignancy invades the epiphysis by way of the canals for the epiphyseal vessels.

### 16.5 APPENDIX 16-1

1104

#### 16.5.1 POSTMORTEM EXAMINATION AND EVALUATION OF BONES

1105

The entire skeleton is rarely examined at necropsy. Instead, the extent of the examination is dictated by the clinical history. Antemortem clinical and radiographic findings are valuable and should be in hand before the postmortem examination is begun, especially for cases suspected of having relatively small localized lesions. It should be remembered that a lesion responsible for lameness may involve the skeletal, muscular, or nervous systems.

Pathologists should routinely examine certain areas of the skeleton. This procedure provides completeness to the necropsy and leads to familiarity with normal osseous structures. At least one long bone should be cut longitudinally and examined at necropsy. This examination should include an assessment of marrow for fat cell stores and hemopoietic activity, thickness of cortical bone, amount and distribution of cancellous bone, thickness and uniformity of metaphyseal growth plates, articular surfaces, and tendon insertions. In small animals, testing bone strength by breaking a rib can be informative, but because of the marked variation in sizes of small animals, this becomes very relative. More important than the strength required to break a rib is noting the degree to which the rib will bend before breaking. Increased pliability might indicate fibrous osteodystrophy. Bony tissues are more readily seen if bone marrow contents are flushed out with a jet of water. Some lesions can be best visualized radiographically. Postmortem radiographs of slabs of bones or entire bones with much of the soft tissue removed can be very informative. Postmortem autolytic changes do not usually pose major problems in the evaluation of the skeleton at necropsy. Postmortem bacterial invasion is less rapid than in most other tissue, and bone marrow cultures can be useful in detecting bacteremia (e.g., salmonellosis). Bones can be fractured at euthanasia and by postmortem transport and handling. Postmortem fracture of bones will not be associated with hemorrhage in bone or adjacent soft tissue. Fracture of bones during euthanasia could be difficult to distinguish from recent fracture, especially if recent antemortem trauma was reported in the history. However, as in a postmortem bone fracture, less blood from hard and soft tissue is expected in agonal fracturing of bones.

#### 16.5.2 POSTMORTEM EXAMINATION AND EVALUATION OF JOINTS

Several large synovial joints, such as the shoulder and hip, should be opened and examined routinely at necropsy to become familiar with the expected age-related changes in cartilage. Septicemic joint disease may not affect these larger joints, and when suspected, many joints should be examined, including the carpal and tarsal joints. Joints should be disarticulated so that articular surfaces, synovial fluid, and all associated structures are clearly visible. Consideration should be given to aspirating synovial fluid before disarticulation

## **Pathologic Basis of Veterinary Disease, 4th Edition**

---

to obtain a sample free of contamination and suitable for culture and analysis that includes viscosity (mucin precipitation), cell count, and cytology. Articular cartilage must be examined as soon as the joint is opened because dehydration of cartilage occurs rapidly on exposure to air. Fine fingerlike proliferations of synovium (villous hypertrophy) are best evaluated if the specimen is submerged in water, saline, or formalin. Microscopic examination of synovium might be required to confirm the presence of synovitis.

## 17 Chapter 17 The Integument

ANN M. HARGIS

PAMELA E. GINN

### 17.1 INTRODUCTION

#### 17.1.1 BASIC FUNCTION, STRUCTURE, AND HOST DEFENSE MECHANISMS OF THE INTEGUMENT

##### 17.1.1.1 FUNCTIONS OF THE SKIN

The skin is not only the largest organ in the body, but one of the most important. Without the skin, terrestrial mammalian life could not exist. The skin has numerous functions, which are listed in [Box 17-1](#). The skin prevents significant loss of fluid and electrolytes (e.g., the stratum corneum barrier), protects against physical and chemical injury (e.g., the stratum corneum barrier, keratin filaments, desmosomal and hemidesmosomal junctions, collagen, and elastic fibers), participates in temperature and blood pressure regulation (e.g., the hair coat, sweat glands, and vascular supply), produces vitamin D (e.g., ultraviolet light photolysis of dehydrocholesterol), serves as a sensory organ (e.g., tactile hairs, Merkel cells, and nerves), and stores fat, water, vitamins, carbohydrates, protein, and other nutrients (e.g., subcutaneous fat). Absorption, although not a primary function, also occurs. In addition, the keratinocyte, a major source of cytokines and antimicrobial peptides, is now considered to be an integral part of the innate and adaptive immune systems protecting against microbial injury and participating in inflammation and tissue repair.

##### 17.1.1.2 MORPHOLOGY OF THE SKIN

The skin is the largest organ in the body and has haired and hairless portions ([Figs. 17-1](#) and [17-2](#)). The skin consists of epidermis, dermis, subcutis, and adnexa (hair follicles and sebaceous, sweat, and other glands). The histologic structure varies greatly among different sites and among different species of animals. The haired skin is thickest over the dorsal aspect of the body and on the lateral aspect of the limbs, and is thinnest on the ventral aspect of the body and the medial aspect of the thighs. Haired skin has a thinner epidermis, whereas nonhaired skin of the nose and footpads has a thicker epidermis ([Figs. 17-1](#) and [17-2](#)). The skin of large animals is generally thicker than the skin of small animals. The subcutis, consisting of lobules of adipose tissue and fascia, connects the more superficial layers (epidermis and dermis) with the underlying fascia and musculature.

##### 17.1.1.2.1 EPIDERMIS

The epidermis is divided into layers based on the morphology of the keratinocyte, the major cell type of the epidermis. The epidermis of haired skin consists of four basic layers (stratum corneum, stratum granulosum, stratum spinosum, and stratum basale) ([Fig. 17-3](#)). The epidermis of hairless skin consists of five layers; the fifth layer is the stratum lucidum, which is located between the stratum granulosum and stratum corneum. Keratinocytes originate from germinal cells in the stratum basale of the epidermis, ascend through the layers of the epidermis, differentiating in each layer until they reach the stratum

1107

1108

## Pathologic Basis of Veterinary Disease, 4th Edition

---

corneum. Keratinocytes are continuously shed from the stratum corneum. The time of transit for a keratinocyte in the stratum basale to shedding at the stratum corneum is approximately 1 month, although this time can be accelerated in some disorders, such as primary seborrhea characterized clinically by scaling.

17.1.1.2.1.1

### Box 17-1 Functions of the Skin

Provides a protective barrier against fluid loss, microbiologic agents, chemicals, and physical injury

Regulates temperature and blood pressure

Produces vitamin D

Acts as sensory organ

Stores nutrients

Absorptive surface

Participates in innate and adaptive immunity and inflammation and repair

**Fig. 17-1 Normal skin, haired, thorax, dog.** The epidermis (*arrow*) in haired skin has an undulating surface but lacks rete ridges. The epidermis in haired skin has fewer nucleated cell layers than the epidermis in nonhaired (hairless) skin such as the nose and footpads ([Fig. 17-2](#)); thus it is referred to as “thin” skin. Hair follicles (*H*), apocrine glands (*A*), and sebaceous glands (*S*) are present. The haired skin is thickest over the dorsal aspect of the body and on the lateral aspect of the limbs, and it is thinnest on the ventral aspect of the body and the medial aspect of the thighs. H&E stain. (Courtesy Dr. Ann M. Hargis, *DermatoDiagnostics*.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The outermost layer of the epidermis is the stratum corneum, which consists of many sheets of flattened, keratinized cells termed corneocytes. Keratin is an intracellular fibrous protein that is in part responsible for the toughness of the epidermis, enabling the epidermis to form a protective barrier. The next layer is the stratum granulosum, which consists of effete cells with basophilic keratohyalin granules. In nonhaired skin, the stratum corneum and stratum granulosum are separated by an additional layer of compacted, fully keratinized cells, the stratum lucidum, best seen in the footpad. Deep to the stratum granulosum is the stratum spinosum, a layer of polyhedral-shaped cells attached to one another by desmosomes. During fixation and processing for microscopic examination, the cells of the stratum spinosum contract, except for the desmosomal attachments. These attachment sites create the appearance of “spines” or intercellular bridges, leading to the name of this layer. The visibility of the intercellular bridges is enhanced when there is intercellular edema of the epidermis. The stratum spinosum in haired areas is thinner in dogs and cats and is thicker in cattle, horses, and pigs. The innermost layer of the epidermis is the germinal layer or stratum basale, which consists of a single layer of cuboidal cells resting on a basement membrane. Intermixed within the basal cell layer are melanocytes, Langerhans' cells, and Merkel cells.

1108

1109

Fig. 17-2 **Normal skin, hairless, footpad, dog.** The epidermis (*E*) in hairless (nonhaired) skin has more numerous nucleated cell layers and more abundant stratum corneum than the epidermis in haired skin; thus it is referred to as “thick” skin. Note the dense zone of compact stratum corneum (*SC*) over the surface. The epidermis and dermal papillae (*D*) interdigitate to form rete ridges (*arrows*). The rete ridges strengthen the attachment between the epidermis and dermis. In the dog, the contour of the epidermal surface follows the epidermal ridges and thus is papillated. H&E stain. (Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

**Fig. 17-3 Schematic diagram of the structure of the skin.** The skin is composed of epidermis (*e*), dermis (*d*), and subcutis (*s*), with adnexa consisting of hair follicles (*hf*), sebaceous glands (*sg*), and apocrine glands (*ag*). **B**, This projection of the epidermis demonstrates the progressive upward maturation of basal cells (*bc*) in the stratum basale (*sb*) through the stratum spinosum (*ss*), stratum granulosum (*sg*) into the cornified squamous epithelial cells of the stratum corneum (*sc*). Melanocytes (*m*), midepidermal dendritic Langerhans' cells (*lc*), and Merkel cells (*mc*) are also present. The subjacent dermis contains small vessels (*v*), fibroblasts (*f*), perivascular mast cells (*pmc*), and dendrocytes (*dc*), potentially important in dermal immunity and repair. (Adapted from Cotran RS, Kumar V, Collins T, Robbins SL: Robbins pathologic basis of disease, ed 6, Philadelphia, 1999, Saunders; and Gawkrödger DJ: Dermatology: an illustrated colour text, ed 2, New York, 1997, Churchill Livingstone.)

Melanocytes, embryologically derived from neural crest cells, are also present in lower layers of the stratum spinosum and produce melanin pigment, giving skin and hair their color. Melanocytic granules are transferred to and distributed in keratinocytes as a caplike cluster of granules between the nucleus and the external surface of the skin to help protect the nucleus from ultraviolet light–induced injury. Langerhans' cells are bone marrow–derived cells of monocyte-macrophage lineage that process and present antigen to sensitized T lymphocytes, thereby modulating immunologic responses of the skin. Langerhans' cells are present in the basal, spinous, and granular layers of the epidermis but have a preference for a suprabasal position. Merkel cells are neuroendocrine cells located in the basal layer that join with keratinocytes via desmosomal junctions. Merkel cells are located in haired and hairless skin, particularly in regions of the body with high tactile sensitivity (digits and lips), and in the outer portion of hair follicles. In some sites, Merkel cells are present in tylotrich pads where they form a Merkel cell—neurite complex. Merkel cells have granules that contain neurotransmitter-like substances (met-enkephalin, vasoactive intestinal peptide, chromogranin A, acetylcholine, calcitonin gene-related peptide, neuron-specific enolase, and synaptophysin). The specific role these substances play in paracrine or autocrine control of keratinocytes or hair follicle epithelial cells remains speculative. Merkel cells also function as slowly adapting mechanoreceptors.

1109

1110

### 17.1.1.2.2

#### Basement Membrane Zone

The epidermis and dermis are separated by a basement membrane. In hairless areas, such as the footpads and nasal planum, this junction is irregular because of epidermal projections that interdigitate with dermal papillae (e.g., rete ridges/a.k.a. rete pegs), thus strengthening the epidermal-dermal attachment by providing resistance to shearing. In densely haired areas, the junction is smoother and has an undulating appearance as the epidermal-dermal attachment is strengthened by the hair follicles. The more sparsely haired skin of pigs has more epidermal-dermal interdigitations (rete ridges) and fewer hair follicles. The basement membrane zone is composed of hemidesmosomes of basal cells (i.e., tonofilaments and attachment plaques), the lamina lucida (plasma membrane, subdesmosomal dense plate, and anchoring filaments), and the lamina densa (i.e., type IV collagen), which also serve to anchor the epidermis to dermis (Fig. 17-4). The importance of the basement membrane in anchoring function is noted in some immune-mediated diseases where antibodies bind to a component in the basement membrane and result in the formation of bullae (see Selected Autoimmune Reactions, Reactions Characterized Grossly by Vesicles or Bullae as the Primary Lesion and Histologically by Vesicles or Bullae within the Basement Membrane [Bullous Dermatoses]). The basement membrane zone also serves as a scaffold for migration of epidermal cells in wound healing and as an initial barrier to invasion of the dermis by neoplastic epidermal cells.

**Fig. 17-4 Schematic diagram of basement membrane structure of the skin.** Keratinocytes attach to each other via desmosomes and to the basement membrane via hemidesmosomes. The projection of the basement membrane zone illustrates the multiple, interconnecting layers of this zone. The most superficial layer consists of the basal layer hemidesmosomes (tonofilaments and attachment plaques). The next layer, the lamina lucida, is an electron-lucent zone composed of the plasma membrane (not labeled), subdesmosomal dense plate, and anchoring filaments. The deepest layer is the lamina densa, an electron-dense zone that consists of type IV collagen. Collagen rootlets extend from the lamina densa for a short distance into the papillary dermis, and microfibrils, long delicate elastic fibrils, blend with underlying elastic structure of the dermis. The interconnecting layers of the basement membrane zone provide an important function in epidermal-dermal adherence, are the site of immune reactant deposition in cutaneous disease ([Table 17-12](#)), and serve as a barrier to invasion by malignant epidermal tumors. *ag*, Apocrine glands; *d*, dermis; *e*, epidermis; *hf*, hair follicles; *s*, subcutis; *sg*, sebaceous glands. (Adapted from Cotran RS, Kumar V, Collins T, Robbins SL: Robbins pathologic basis of disease, ed 6, Philadelphia, 1999, Saunders; and Rubin E, Farber JL: Pathology, ed 3, Philadelphia, 1999, Lippincott-Raven.)

17.1.1.2.3

### Dermis

The dermis (corium), consisting of collagen and elastic fibers in a glycosaminoglycan ground substance, supports hair follicles, glands, vessels, and nerves. By convention, the dermis is generally subdivided into superficial and deep layers that blend together without a clear line of demarcation. The superficial dermis conforms to the contour of the epidermis and generally supports the upper portion of the hair follicle and sebaceous glands. It is composed of fine collagen fibers and is wider in the skin of cattle and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

horses than in the skin of dogs and cats. The deep dermis supports the lower portion of the hair follicle and apocrine glands and is composed of collagen bundles larger than those in the superficial dermis. Smooth muscle fibers of the arrector pili muscle attach the connective tissue sheath of the hair follicle to the epidermis and are responsible for causing the hair to stand erect. Skeletal muscle fibers from the cutaneous muscle extend into the lower dermis and are responsible for voluntary skin movement. Mast cells, lymphocytes, plasma cells, macrophages, and rarely eosinophils and neutrophils can be found in normal dermis. These cells are bone marrow derived—cells and arrive via the blood vascular system; thus they are typically concentrated around small superficial blood vessels.

17.1.1.2.4

### Vessels and Nerves

Cutaneous arteries give rise to three vascular plexuses: deep, middle, and superficial. The deep plexus supplies the subcutis and deep portions of follicles and apocrine glands; the middle plexus supplies the sebaceous glands, midportion of follicles, and arrector pili muscles; and the superficial plexus supplies the superficial portions of follicles and epidermis. Lymph capillaries arise in the superficial dermis and connect with a subcutaneous plexus. The lymph vessels then converge to form larger channels that eventually reach peripheral lymph nodes.

1110

1112

The skin is an important sensory organ containing millions of microscopic nerve endings that perceive itch, pain, temperature, pressure, and touch (Fig. 17-5). The nerve endings consist of Meissner's corpuscles, pacinian corpuscles (Pacini's corpuscles), free sensory nerve endings, and mucocutaneous end organs (similar to Meissner's corpuscles but located in mucocutaneous skin). These nerve endings are minute, and the free sensory nerve endings are so delicate that they require special staining techniques, such as silver impregnation, to be visualized microscopically. The sensations of itch, pain, touch, temperature, and displacement of body hair are detected by the free sensory nerve endings. Itching, a form of mild pain that promotes the desire to scratch, is one of the most common reasons animals are presented to veterinarians. The sensations of touch and pressure are detected by Meissner and Pacini's corpuscles. Sensations detected by free sensory nerve endings and by the corpuscles are transmitted to the spinal cord via the dorsal root ganglia. Sensory fibers to the facial area are supplied by the trigeminal nerve. Motor fibers (adrenergic and cholinergic) are supplied by the sympathetic component of the autonomic nervous system (Fig. 17-5). Adrenergic fibers travel from the spinal cord through postganglionic fibers in peripheral nerves and arborize into plexuses that innervate blood vessels, arrector pili muscles, and apocrine sweat glands. Stimulation by these adrenergic fibers causes vasoconstriction and piloerection (raising of the hair shafts). Cholinergic fibers travel from the spinal cord and arborize into plexuses that innervate the eccrine sweat glands. Stimulation of these fibers in human beings causes widespread eccrine sweating, important in thermoregulation and recognized clinically as "beads of sweat" on the skin. Because the eccrine ducts open directly on the surface of the skin, the secretion is more easily seen clinically. This phenomenon does not occur in dogs or cats because they lack eccrine glands in haired skin. However, cholinergic and to a lesser degree adrenergic fiber stimulation in dogs and cats causes sweating of the eccrine glands of footpads at times of excitement or agitation. Physiologic control of sweating in horses is primarily neural due to adrenergic fiber stimulation of apocrine glands, but a humoral component mediated by adrenergic agonists released from the adrenal medulla into the circulation also plays a role during exercise. Eccrine sweat glands have not been described in the horse. The only other domestic animal in which apocrine gland secretion is thought to play a thermoregulatory role is cattle, but sweating is not typically clinically visible except in horses.

1112

1113

**Fig. 17-5 Schematic diagram of cutaneous innervation.** Unmyelinated cutaneous nerve endings transmit sensations of touch, pressure, temperature, pain, and itch via dorsal root ganglia to the central nervous system. Motor fibers in skin are supplied by the autonomic nervous system. Adrenergic fibers activate arterioles, arrector pili muscles, and apocrine glands; cholinergic fibers stimulate eccrine glands. (Adapted from Ackerman AB: Histologic diagnosis of inflammatory skin diseases, Philadelphia, 1978, Lea and Febiger.)

### 17.1.1.2.5 Subcutis (Panniculus, Hypodermis)

The subcutis attaches the dermis to subjacent muscle or bone and consists of adipose tissue and collagenous and elastic fibers, which provide flexibility. Adipose tissue insulates against temperature variation and, in the case of footpads, serves in shock absorption.

### 17.1.1.2.6 Adnexa

#### 17.1.1.2.6.1 Hair Follicles

The growth of hair occurs within hair follicles in a sequence of stages (Fig. 17-6). These stages include hair genesis, growth, maturation, and loss. In the anagen stage of the hair cycle, mitotic activity and growth occur. The catagen stage is a transitional phase during which cellular proliferation ceases. The follicle then enters a resting stage, telogen, after which mitotic activity and new hair production resumes. The exogen stage is the phase in which the old hair is shed. In many animals hair follicle growth occurs in cycles, resulting in periodic loss or shedding of the hair coat. The reason the

## Pathologic Basis of Veterinary Disease, 4th Edition

hair growth occurs in cycles is not clear. Some hypotheses include that the cycle provides the ability: (1) to shed fur to cleanse the body surface, (2) to adapt and change body cover in response to changing environment (winter to summer) or social conditions, or (3) to protect against malignant transformation that might occur in a rapidly dividing tissue. The regulation of hair cycling is exceedingly complex and incompletely understood. Factors that play a role include genetics, photoperiod, temperature, nutrition, hormones, health status, and neural mechanisms. Genetic factors determine the hair shaft length (e.g., short-haired versus long-haired breeds of dogs). The exact signals that control the hair cycle have not been identified; however, growth factors, such as epidermal growth factor, fibroblast growth factor, hepatocyte growth factor, platelet-derived growth factor, transforming growth factor- $\beta$  (TGF- $\beta$ ), and insulin-like growth factor, have been localized to the skin and hair follicles. These growth factors probably play a crucial role in regulation of the hair cycle and follicle growth.

**Fig. 17-6 Schematic diagram of the hair cycle.** **A**, Anagen. During this growing stage, hair is produced by mitosis in epithelial cells covering the apex of the follicular papilla (dermal papilla), which is enveloped by hair matrix cells at the hair bulb. **B**, Early catagen. In this transitional stage, a constriction occurs at the hair bulb, and the hair shaft above this becomes a “club hair.” **C**, Catagen. The distal follicle becomes thick and corrugated and pushes the hair outward. **D**, Telogen. This is the resting stage in which the dermal (follicular) papilla separates and an epithelial strand shortens to form a secondary germ. **E**, Early anagen. The secondary germ grows down to enclose the dermal (follicular) papilla, and a new hair bulb forms. **F**, Exogen. This refers to the shedding of the old hair shaft. **G**, Anagen. The hair elongates as growth continues. Note that the anagen hair bulbs are located deeper in the dermis than the catagen and telogen hair bulbs. (**A through G**, From Scott DW, Miller WH Jr, Griffin CE: Muller and Kirk's small animal dermatology, ed 6, Philadelphia, 2001, Saunders.)

Photoperiod acts via the hypothalamus, pituitary, and pineal glands, which secrete tropic hormones, such as melatonin and gonadal, thyroid, and adrenal hormones, that also influence hair growth. Some hormones, such as thyroid and growth hormone, stimulate hair growth, whereas excessive levels of estrogen or glucocorticoids suppress hair growth. The cells in the follicular papilla (sometimes called dermal papilla) regulate epithelial growth and are probably the target of the tropic hormones. Nutrition and health status have a significant influence on hair growth and quality. Hair is largely composed of protein. Thus diets low in protein or disease states associated with severe protein loss result in poor quality hair coat. Animals in poor health have larger numbers of hair follicles in telogen, and because telogen hairs are more easily shed than anagen hairs, animals in poor health tend to shed more heavily than healthy animals. Also, in disease states, cuticle formation can be defective, resulting in a dull or dry hair coat. It is also thought that the hair cycle is influenced by the nervous system. Evidence of such is implied by the abundant nerve supply of the hair follicle, the high density of Merkel cells in the hair follicle epithelium, and facts that keratinocytes express several neurotransmitter and neuropeptide receptors whose stimulation can alter keratinocyte proliferation and differentiation. Indirect influence by autonomic nerves could also be mediated by alteration of hair follicle blood flow and thus of oxygen and nutrient supply.

1113

1114

**Fig. 17-7 Schematic diagram of the skin and simple and compound hair follicles.** For the purpose of simplification, the vascular supply is illustrated on one face only. Note the simple hair follicle (*right*) and the compound hair follicle (*left*). Simple follicles consist of one large primary follicle with the hair bulb in the dermis or subcutis (depth varies with species), and with sebaceous and apocrine glands, and arrector pili muscles. Compound follicles consist of a large primary follicle and smaller secondary follicles. The hair bulbs of secondary follicles are located more superficially in the dermis than the hair bulbs of primary follicles. Secondary follicles may have sebaceous glands but lack apocrine glands and arrector pili muscles. (From Dellman DH, Brown EM: Textbook of veterinary histology, ed 3, Philadelphia, 1987, Lea and Febiger.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Forms of hair follicles vary in different animals (Fig. 17-7). Cattle and horses have evenly distributed simple follicles with one large (i.e., primary) follicle, usually with sebaceous and apocrine glands and arrector pili muscles. Pigs have simple follicles grouped in clusters. Goats, dogs, and cats have compound follicles that consist of primary follicles and smaller secondary follicles. Sheep have simple follicles in hair-growing areas and compound follicles in wool-growing areas. Primary follicles have the hair bulb rooted more deeply in the dermis than secondary follicles. The depth of the hair bulbs varies with species. In dogs and cats, the anagen hair bulbs of primary follicles are at the dermal-subcutaneous junction, whereas in horses and cattle the anagen hair bulbs are in the mid dermis. In all species, the bases of telogen follicles are more superficially located than the bases of anagen follicles. Typically, primary and secondary hair shafts emerge through a common follicular opening. Tactile hairs include sinus and tylotrich hairs. Sinus hairs, also termed vibrissae, arise in simple follicles with a blood-filled sinus located between the inner and outer layers of the dermal sheath. Sinus hairs generally occur on the nose, above the eyes, on the lips and throat, and on the palmar aspect of the carpus of cats. Sinus hairs function as mechanoreceptors (i.e., touch receptors). Tylotrich hairs also function as mechanoreceptors and are scattered among the regular body hairs. The arrector pili muscles extend from the connective tissue sheath of the hair follicles at the junction of the middle and inferior portion of the follicle and attach to the superficial dermis. The arrector pili smooth muscles are oriented almost perpendicularly to the wall of the follicle, and are well developed on the back of animals, especially dogs. Muscle contraction causes erection of hairs and expression of the contents of sebaceous glands.

17.1.1.2.6.2

### Sweat Glands

There are two basic types of sweat glands: apocrine glands and eccrine glands. Apocrine glands are located throughout haired areas of skin in domestic animals and are tubular- or saccular-coiled glands. The ducts of the apocrine glands open in the superficial portion of the hair follicle; thus these glands are also called “epitrichial glands.” The glands are lined by secretory cuboidal to low columnar epithelium surrounded by contractile myoepithelial cells. Other apocrine glands include the interdigital glands of small ruminants, glands of the external ear canal and eyelids of domestic animals, anal sac glands of dogs and cats, and the mental organ of pigs. Eccrine glands are merocrine in secretion and, in contrast to ducts of apocrine glands, the ducts open directly onto the surface of the epidermis. Thus eccrine glands are also called “atrichial glands.” They are tubular glands lined by cuboidal epithelium surrounded by myoepithelium and are confined mainly to footpads of dogs and cats, frog region of ungulates, carpus of pigs, and nasolabial region of ruminants and pigs.

1114

1115

17.1.1.2.6.3

### Sebaceous glands

Sebaceous glands are simple, branched, or compound alveolar glands that undergo holocrine secretion, with ducts opening into hair follicles except at some mucocutaneous junctions where the glands open on the surface of the skin (e.g., meibomian gland/a.k.a. tarsal gland). Well-developed sebaceous glands are found in the supracaudal gland of dogs and cats; infraorbital, inguinal, and interdigital regions of sheep; the base of the horn of goats; the anal sac glands of cats; the preputial glands of horses; and the submental organ of cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.1.1.2.6.4

### Specialized structures

Anal sacs are specialized cutaneous structures that are especially prone to develop lesions. Anal sacs are bilateral diverticula located between internal and external anal sphincter muscles in dogs and cats, and have ducts that open onto the anus at the level of the anocutaneous junction. Ducts and sacs are lined by stratified squamous epithelium. In cats, the sac wall has sebaceous and apocrine glands, but in dogs the wall has only apocrine glands. The anal sacs can become distended with secretory products, rupture following trauma, and cause bacterial infection and chronic inflammation (foreign body reaction) in contiguous tissues.

Hepatoid (i.e., circumanal or perianal) glands occur most commonly in the skin around the anus and are also present in skin near the prepuce, tail, flank, and groin. These glands have nonpatent ducts and are composed of peripheral reserve cells that surround lobules of differentiated cells resembling hepatocytes, resulting in the name “hepatoid” glands.

The claws of dogs and cats shield the third phalanx and consist of a wall (i.e., dorsal and lateral sides) and sole (i.e., ventral side), both of which are stratified squamous keratinizing epithelium. The wall consists of hard keratin and the sole of softer keratin. The dermis of the claw consists of dense collagen, elastic tissue, and blood vessels that can bleed profusely if the claw is trimmed too short. The claw fold is a fold of skin that covers the wall laterally and dorsally for a short distance. Hooves consist of the wall, sole, and frog in solipeds; and a wall, sole, and prominent bulb in ruminants and pigs. The hoof wall comprises three structurally distinct layers (i.e., stratum externum, stratum medium, and stratum internum), which are formed by the proliferation and downward movement of epidermal cells arising from a specialized junction of the epidermis and dermis, a region known as the coronary band. The stratum internum interdigitates with the dermal collagen, thereby anchoring the hoof to the dermis. In general, the deeper portion of the dermis blends with the periosteum of the third phalanx.

The digital pads of dogs and cats have a thick epidermis composed of all layers, including the stratum lucidum. The surface is covered by compacted layers of stratum corneum and is smooth in the cat; however, in the dog, the surface is covered by conical papillae that conform to the outline of the epidermal surface (Fig. 17-2). The epidermis and dermis interdigitate via rete ridges and dermal papillae, thus providing resistance to shear forces. Eccrine (atrichial) glands are present in the dermis and the adipose tissue. Lobules of adipose tissue that act as a cushion are subdivided by collagenous stroma and elastic tissue.

The chestnuts and ergots of the horse are considered to be vestiges of the first, second, and fourth digits. Chestnuts are located in the supracarpal and tarsal area on the medial surface of the limbs, and the ergot is located at the flexion of the fetlocks (metacarpophalangeal articulation). Chestnuts and ergots are histologically similar, and consist of compact stratum corneum covering thick cellular layers of the epidermis. The rete ridges are long and interdigitate with long dermal papillae.

17.1.2

### PORTALS OF ENTRY INTO THE SKIN

Normal intact skin has many natural defenses and barriers that render it impenetrable to most organisms and protect the body from a variety of other types of insults that include pressure, friction, mild mechanical trauma, temperature extremes, ultraviolet light exposure, and chemical absorption.

## Pathologic Basis of Veterinary Disease, 4th Edition

The route by which an infectious agent gains entry into the body is called the portal of entry (Box 17-2). Many pathogens can only cause disease when entering the body via their specific portal of entry. A few pathogens, such as hookworm larvae, are able to penetrate intact normally functioning skin. Dermatophytes are able to colonize the cornified structures (hair, claws) and the stratum corneum, and cause disease without ever entering living tissue. Clinical disease in a dermatophyte infection is the result of the host's reaction to the organism and its byproducts. The skin only becomes an efficient portal of entry for microorganisms when the barrier is damaged by trauma, excessive moisture, heat or cold, or by disruption of the normal flora of the integument. A number of microorganisms (e.g., *Staphylococcus intermedius*, *Streptococcus* sp., *Corynebacterium pseudotuberculosis*, *Pasteurella* sp., *Proteus* sp., *Pseudomonas* sp., and *Escherichia coli*) gain entrance to the body by either entering through natural pores, such as hair follicles or glands with ducts that traverse the epidermis, or by the parenteral route, which includes all types of breaks in the skin including injections, insect bites, and other types of wounds. Organisms that are able to inhabit hair follicles, such as mites or bacteria, gain entry to the body when the wall of the follicle is ruptured, leading to emptying of follicular contents into the dermis. Similarly, rupture of glands or ducts can lead to entry of microorganisms. From here, infectious agents can stimulate a robust host immune response or possibly spread to other areas of the body by gaining entry to the blood stream or traveling to regional and distant lymph nodes via lymph flow.

Migration from ganglion along sensory nerves via axonal flow to epithelial cells

### 17.1.2.1.4 SUPPORT STRUCTURES

Penetrating trauma from bone fracture

Extension of tumor or infection from adjacent lymph node, gland, muscle, or bone

Intact skin with its waterproof barrier provides some protection against weak acids and alkali substances and water-soluble compounds, but certain lipid-soluble compounds can be absorbed directly through intact skin as can some artificially engineered gases developed for chemical warfare. Ultraviolet radiation can damage the skin by direct exposure if the body's natural defenses, such as the hair coat and melanin pigments, are not present or are inadequate. The lesions of actinic dermatitis (see Disorders of Physical, Radiation, or Chemical Injury; Solar Dermatitis, Keratosis, and Neoplasia) typify the effects of chronic exposure to ultraviolet radiation. In addition to actinic dermatitis, squamous cell carcinomas, hemangiomas, and hemangiosarcomas have an increased tendency to develop in skin chronically damaged by ultraviolet radiation.

The dermal capillaries can be a portal of entry to the skin via the hematogenous route. Embolization of infectious agents, such as bacteria (*Erysipelothrix rhusiopathiae* [diamond skin disease]) or fungi (systemic infection with *Blastomyces dermatitidis*) can damage the skin via this route during hematogenous dissemination. Tumor cells (hemangiosarcoma) can also embolize to the skin and lead to metastatic tumor foci or possible cutaneous infarction. The hematogenous route is also most often the delivery system for drugs (adverse cutaneous reactions to the administration of trimethoprim-potentiated sulfonamides; photosensitization dermatitis that occurs with phenothiazine ingestion) and toxins (gangrenous ergotism caused by the mycotoxin of *Claviceps purpurea*) to reach the skin.

Rarely an infectious agent that is neurotropic can migrate from a ganglion along sensory nerves via axonal flow to the skin (reactivation of feline herpesvirus 1 infection in cats resulting in ulcerative facial dermatitis). The skin can also be secondarily infected or traumatized or damaged by extension of pathologic processes affecting adjacent support structures such as bone, muscle, lymph nodes, or glands (locally invasive mammary gland carcinoma resulting in cutaneous ulceration).

### 17.1.3 HOST DEFENSE MECHANISMS AGAINST INJURY

The skin is a complex organ composed of many integrated components structurally and functionally designed to protect the host. Host defenses against injury principally consist of three broad mechanisms: (1) physical defense, (2) immunologic defense, and (3) repair mechanisms. The most critical defense is the barrier derived from the more superficial layers of the skin, which include the stratum corneum, epidermis, basement membrane, and superficial dermis. Without these outer layers of the skin, animals cannot survive (consider, for example, the deleterious effects of extensive burns and immune-mediated diseases, such as pemphigus vulgaris). One of the most important cells in the skin is the keratinocyte. The keratinocytes terminally differentiate to form the stratum corneum, the outermost barrier of the skin. The keratinocytes produce keratin filaments, desmosomes, and hemidesmosomes, providing structural integrity to the cytoplasm and an interconnecting network that anchors the keratinocytes to each other and the basement membrane. Keratinocytes produce cytokines (interleukin-1 [IL-1], IL-6, IL-8, IL-3, tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ], colony-stimulating factors) and growth factors (TGF- $\alpha$  TGF- $\beta$ , platelet-derived growth factor [PDGF],

1116

1117

## Pathologic Basis of Veterinary Disease, 4th Edition

fibroblast growth factor [FGF]), thus participating in innate and adaptive immunity and in the communication between the two. Keratinocytes also dissolve desmosomes and hemidesmosomes and form actin filaments so they can migrate to cover skin wounds and then proliferate to regenerate the wounded skin. Keratinocytes thus not only orchestrate the activities of the skin but also serve as many members of the orchestra.

### 17.1.3.1 PHYSICAL DEFENSE MECHANISMS

#### 17.1.3.1.1 Barrier Functions

Barriers of the skin against physical injury are listed in [Box 17-3](#). The hair coat, particularly the long dense hair coat of some dogs and cats, serves as a physical barrier to temperature extremes, ultraviolet radiation, and minor trauma. The hair coat also sheds water as a result of the lipids provided by sebaceous gland secretion. Vibrissae, or tactile hairs, and sensory neurons provide awareness of the physical environment, allowing the animal to make appropriate reactions for survival, such as reflex responses to heat and other noxious stimuli. Claws, especially on cats, serve as a quite effective barrier against predators by providing traction for climbing and serve as weapons to be used against aggressors. Horns of cattle, sheep, and goats also provide some physical defense capabilities.

The stratum corneum is an exceedingly important component of the barrier, imparting protection from the exterior and preventing water loss from the interior. The stratum corneum is the “bricks and mortar” of the barrier. The bricks are the flattened, cornified cells that are eventually shed from the surface through daily frictional trauma and that are continually renewed by regeneration of basal cell keratinocytes. The mortar consists of intercorneocyte lipids derived from lipid membranes extruded from the lamellar granules of keratinocytes in the outer granular layer. About 90% of the corneocyte is tightly packed keratin filaments arranged parallel to the skin surface; the remaining 10% is the cornified cell envelope, a resilient protein-lipid polymer. The strength of the protein component is the result of cross-linking of structural proteins (e.g., keratin intermediate filaments, desmosomal proteins, and others) by disulfide and isopeptide bonds. The lipid component surrounds the protein component to which it is covalently bound and provides adhesion of the cornified cells (i.e., bricks) to the intercellular lipids (i.e., mortar). Layers of the corneocytes and their corneocyte envelope (i.e., bricks), and intercellular lipids (i.e., mortar) form a tough and resilient protective barrier. The waterproofing and repellency of the stratum corneum is in part provided by the keratinocyte and sebum-derived lipids. Secretion from apocrine glands in cattle and horses provides defense against excessive heat.

#### 17.1.3.1.1.1 Box 17-3 Host Defense Mechanisms against Injury: Physical Defense Mechanisms

##### 17.1.3.1.1.1.1 BARRIER FUNCTIONS

Hair follicles: Physical and thermal

Tactile hairs and neurons: Sensory

Claws and horns: Physical defense

Stratum corneum: Barrier function

Adnexal glandular secretions: Barrier function

## Pathologic Basis of Veterinary Disease, 4th Edition

17.1.3.1.1.1.2

Apocrine glands horses and cattle: Defense against excessive heat

Melanin: Defense against ultraviolet radiation

Basement membrane zone: Filter to macromolecules, and barrier to invasion of neoplastic epidermal cells

Panniculus: Barrier against temperature extremes

### RESISTANCE TO MECHANICAL FORCES

Hair follicles and epidermal-dermal interdigitations: Anchor epidermis to dermis

Stratum corneum: Corneocyte, corneocyte envelope, and intercellular lipid adhesion

Desmosomes and hemidesmosomes: Intercellular and basement membrane adhesion

Basement membrane: Anchors epidermis to dermis

Collagen and elastic tissue: Resilience, strength, and support of adnexa

Panniculus: Shock absorption, facilitates movement, anchors dermis to fascia

Other barrier functions of the skin include defense against antioxidant injury provided by vitamin E in sebaceous gland secretion, and defense against ultraviolet light provided by the hair coat and also by melanin pigment in keratinocytes. The cap of melanin pigment over the nucleus helps protect the nucleus (and its nucleic acid) against ultraviolet light-induced injury by scattering and absorbing ultraviolet light rays. The basement membrane zone serves as an initial barrier to invasion of the dermis by neoplastic epidermal cells. The panniculus through its insulating properties serves as a barrier against cold temperatures.

1117

17.1.3.1.2

### Resistance to Mechanical Forces

1118

Anatomic features of the skin that provide resistance to physical injury are listed in [Box 17-3](#). Hair follicles help anchor the epidermis to the dermis, as do epidermal-dermal interdigitations, thus these interdigitations are most numerous in nasal planum and footpad where hair follicles are absent and resistance to shearing force is necessary. Host defense against mechanical injury is also provided by the resilience of the cornified envelope due in part to cross-linked peptides, such as keratin intermediate filaments, and adhesion of cornified envelope and intercellular lipids. The keratinocytes contain keratin filaments and form desmosomal junctions with adjacent cells ([Fig. 17-4](#)). The keratin filaments perform a structural role (i.e., cytoskeletal) in the cells, and the desmosomes promote adhesion of epidermal cells and resistance to mechanical stresses. The desmosomes in the outermost stratum corneum undergo proteolytic degradation allowing individual corneocytes to shed. The basement membrane anchors the epidermis to the dermis providing structural integrity against trauma. Collagen and elastic tissue provide resilience and strength to the skin and support for the vessels, nerves, and adnexa. The panniculus protects against surface trauma by providing some shock absorption (e.g., footpads), by facilitating movement, and by anchoring the dermis to fascia. Thus the various components of the epidermis, dermis, adnexa, and panniculus provide a flexible interconnecting framework to protect the host against mechanical injury.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.1.3.2 IMMUNOLOGIC DEFENSE MECHANISMS

#### 17.1.3.2.1 Innate Immunity

Innate immunity is a primitive, highly conserved response that quickly detects and impairs pathogens and harmful environmental stimuli encountered daily in life and does not require antigen-specific receptors. Innate immunity protects the host during the first 7 days of exposure to a pathogen before development of an adaptive immune response, and also initiates and assists the adaptive immune response (Table 17-1). The diversity of microorganisms requires equal diversity in host defense responses. The first phase of innate host defense consists of the barrier of the stratum corneum, which prevents pathogen adherence and provides an antimicrobial surface consisting of antimicrobial peptides and fatty acids. The antimicrobial peptides (e.g.,  $\beta$ -defensins and cathelicidins) are effective against many organisms including viruses, bacteria, protozoa, and insects, and probably kill some of these pathogens by damaging their lipid membranes. The surface barrier also includes normal flora of nonpathogenic bacteria that competes with pathogenic microorganisms for nutrients and for attachment sites on cells. The normal flora also produces antimicrobial substances that prevent pathogen colonization. Because the dry cornified surface is such an effective barrier to pathogens, a wound or abrasion is usually necessary for a pathogen to gain entrance. If the epidermis sustains injury or if a microorganism otherwise penetrates the surface barrier, it is met by the second phase of innate host defense, namely tissue macrophages and other immune cells that by cell surface receptors contact and bind many types of pathogens. A significant challenge to the innate immune system is for the host to differentiate large numbers of pathogen antigens from self-antigens with the use of a limited number of receptors. It is now known that pathogen recognition is mediated by pattern-recognition receptors, which recognize molecular structures (i.e., pathogen-associated molecular patterns) common to broad classes of pathogens and that efficiently differentiate pathogen antigens from self-antigens.

1118

1119

Table 17-1 Innate Immunity Host Defense Mechanisms

Stratum corneum barrier	Prevents pathogen adherence and provides antimicrobial surface
Macrophages (dendritic cells) with pattern-recognition receptors	Recognize broad classes of pathogens, differentiate pathogen antigens from self-antigens, initiate Toll signaling pathway, and secrete cytokines, facilitating inflammation and innate immunity
Toll signaling pathway	Promotes expression of large numbers of genes, resulting in production of cytokines, chemokines, and adhesion molecules important in inflammation and innate immunity
Macrophages and neutrophils	Recognize, ingest, and destroy pathogens
Endothelial cells	Express adhesion molecules and trigger kinin and coagulation systems, facilitating influx of plasma proteins and migration of leukocytes (cell trafficking) necessary to control infection
Coagulation system	Forms blood clot in case of injury to control blood loss and prevents microorganisms from entering the blood stream
Complement enzyme cascade	Recruits inflammatory cells, opsonizes pathogens, and kills some pathogens
Lipid mediators	Increase vascular permeability and induce influx and activation of leukocytes sustaining inflammatory responses
Innate immunity protects the host in the first 7 days of exposure and does not require antigen-specific receptors but does not provide protection to later reexposure.	

A few examples of pathogen-associated molecular patterns include lipopolysaccharide (most gram-negative bacteria), lipoproteins (non-spore-forming, anaerobic, gram-positive rods), peptidoglycan

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(gram-positive bacteria); CpG motifs (mostly bacterial pathogens), lipoarabinomannan (mycobacteria), mannans and zymosan (yeast), and heat shock proteins (bacteria, fungi, algae, protozoa). Most pattern-recognition receptors act by stimulating signaling pathways, such as the Toll signaling pathway. The Toll signaling pathway is a phylogenetically ancient signaling pathway conserved in plants, insects, and mammals, which translates injury mediated by microorganisms or trauma into biochemical signals that rapidly optimize host defense. This signaling pathway is initiated when pathogen-associated molecular patterns are expressed by microorganisms, initiating a cascade of cytokine and chemokine release. These patterns are recognized by pattern-recognition receptors on the surface of macrophages and dendritic cells. Once triggered, the pathogen-receptor complex recruits an important adaptor molecule, called MyD88, which through a series of less well-understood intracellular signaling steps eventually frees a crucial molecule in host defense, known as NF kappa B, from its sequestered cytoplasmic location in the activated cell to migrate to the nucleus, where it acts as a transcription factor promoting the expression of large numbers of genes resulting in production of cytokines, chemokines, and adhesion molecules important in inflammation and the innate immune response. Thus the important outcome of pathogen-receptor binding is activation of macrophages and dendritic cells and others responsible for host defense, such as lymphocytes, to release cytokines and chemokines (e.g., IL-8 and IL-1), to recruit neutrophils and monocytes to the site of infection, and to activate the arachidonate cascade. Both macrophages and neutrophils play a key role in innate immunity by recognizing, ingesting, and destroying pathogens without the aid of the adaptive immune response.

The complement enzyme cascade, activated rapidly in response to many types of injury, also facilitates the elimination of pathogens by producing proteins (C3b and C4b) that opsonize the surface of pathogens. Opsonization enhances phagocytosis, the recruitment of additional phagocytes, and the killing of some pathogens. After phagocytosis, macrophages and neutrophils kill pathogens via lysosomal enzymes, toxic oxygen-derived products, toxic nitrogen oxides, and antimicrobial peptides, enzymes, and competitors. Cytokines (IL-1, IL-6, and TNF- $\alpha$ ) also produced by macrophages cause fever, synthesis of acute-phase response proteins, and leukocytosis in the acute inflammatory response. Fever is beneficial to host defense because most pathogens grow better at temperatures lower than those associated with fever, and host cells are protected from harmful effects of some cytokines at temperatures elevated above normal body temperature (i.e., above 37° C). The acute-phase response proteins can opsonize a broad range of pathogens and can also activate the complement cascade, making pathogens more susceptible to phagocytosis and killing by macrophages and neutrophils. Finally, cytokines cause leukocytosis by increasing the number of circulating neutrophils available to migrate to the site of the pathogen and participate in phagocytosis.

Cytokines and other mediators released by activated immunocytes induce an acute inflammatory response (see [Chapter 3](#)) resulting in the five cardinal signs of inflammation—heat, pain, redness, swelling, and loss of function. The acute inflammatory response is characterized by changes in local blood vessels including: (1) vasodilation of arterioles, which causes increased blood flow at reduced velocity to capillary beds and postcapillary venules, (2) activation of endothelial cells to express adhesion molecules to bind circulating leukocytes so they can stop circulating, attach to the endothelium, and then migrate to the site of inflammation, and (3) increased vascular permeability that enhances the accumulation of plasma proteins (e.g., fibrinogen, complement) at the site of inflammation.

Activated endothelial cells can also trigger activation of the kinin and coagulation systems. The kinin system causes pain via production of bradykinin and substance P (i.e., activation of sensory nerve fibers) and enhances the acute inflammatory response by increasing vascular permeability. The coagulation cascade promotes blood clotting, thus preventing the spread of pathogens via the vasculature. Once initiated, the innate immune response helps to start the antigen-specific immune response (i.e., adaptive

## Pathologic Basis of Veterinary Disease, 4th Edition

---

immunity). Innate immunity is crucial to protecting the host in the early days of infection; however, pathogens can evade innate immunity, and innate immunity does not lead to immunologic memory characteristic of adaptive immunity.

17.1.3.2.2

### The Interaction Between Innate and Adaptive Immunity

The link between innate and adaptive immunity is complex; however, IL-1 is proposed to be particularly important. If the epidermis sustains injury or if a microorganism penetrates the surface barrier, it is quickly met by an arsenal of stored IL-1 $\alpha$  within the keratinocytes and stratum corneum. IL-1 $\alpha$  induces the expression of more than 90 genes regulating adhesion molecules, chemokines, cytokines, proteolytic enzymes, and matrix proteins in various cell types, including keratinocytes, endothelial cells, and fibroblasts. The induction of gene expression of this magnitude is done through the activation of the Toll

1119

signaling pathway. Other signaling pathways are also activated by the binding of IL-1 to its receptor, further amplifying the inflammatory events associated with IL-1 activation. These events include: (1) stimulation of keratinocyte synthesis of cytokines and chemokines, (2) Langerhans' (i.e., dendritic) cell migration from epidermis to dermis and eventually to skin-associated lymph nodes, and (3) the expression of endothelial adhesion molecules (i.e., E-selectin, intercellular adhesion molecule-1 [ICAM-1], and vascular cell adhesion molecule-1 [VCAM-1]). These events recruit a subpopulation of memory T lymphocytes bearing cutaneous lymphocyte antigen (CLA) on the cell surface, and this molecule mediates passage of lymphocytes out of postcapillary venules. Thus IL-1 participates in both the innate and adaptive immune system.

1120

17.1.3.2.3

### Acquired (Adaptive) Immunity

Whereas innate immunity works immediately to detect and destroy microorganisms, acquired or adaptive immunity develops later because the lymphocytes that contribute to adaptive immunity specific for the invading pathogen must increase in number by clonal expansion. The major components of the cutaneous adaptive immune system include keratinocytes, dendritic antigen-presenting cells (Langerhans' cells and dermal dendritic cells), lymphocytes, and endothelial cells (Table 17-2). The adaptive-immune response is initiated by a stimulus (e.g., microbial invasion, contact with environmental allergens, injury, or tumor growth), at which time the bone-marrow derived antigen-processing and antigen-presenting cells (Langerhans' cells in the epidermis and dendritic cells in the perivascular dermis) ingest and process the antigen. The major function of Langerhans' cells and dermal dendritic cells is antigen processing and presentation; thus these cells are referred to as "professional antigen processing and presenting cells." Langerhans' and dermal dendritic cells reexpress the ingested and processed antigen on their cell surfaces, and migrate via afferent lymphatics to the paracortical areas of skin-associated lymph nodes, where they arrive as mature and powerful antigen-presenting cells. These skin-derived dendritic cells then initiate a pathogen-specific protective immune response by presenting antigen to the naïve T lymphocytes. Langerhans' cells also produce cytokines (e.g., IL-1 and TNF- $\alpha$ ), thus participating in up-regulation of inflammatory and immune responses in the skin.

Table 17-2 Adaptive Immunity Host Defense Mechanisms

Langerhans' cells in epidermis and dendritic cells in dermis	Ingest and process antigen; present antigen to sensitized T lymphocytes at site of injury; and produce cytokines that up-regulate inflammation and immune responses
T lymphocytes	After stimulation by antigen-presenting cells in lymph node, migrate back to the site of injury
CD8 (cytotoxic lymphocytes)	Recognize antigen expressed on the cell surface and kill the cell (cytotoxic lymphocytes); responsible for killing neoplastic cells, some bacteria and parasites, and all viruses that replicate inside cells
CD4 T <sub>H</sub> 1	Activate macrophages, helping to control infection by intracellular bacteria
CD4 T <sub>H</sub> 2	Activate B lymphocytes, helping eliminate extracellular pathogens
B lymphocytes	Secrete immunoglobulin, providing defense against pathogens (often bacteria) in extracellular spaces
Endothelial cells	Express adhesion molecules and bind to stimulated T lymphocytes
Keratinocytes	Produce cytokines and growth factors up-regulating or down-regulating inflammation and immune responses
Cytokines, chemokines, and adhesion molecules	Contribute as in innate immune response
Adaptive (acquired) immunity develops after innate immunity because the lymphocytes that contribute to adaptive immunity specific for the invading pathogen must increase in number by clonal expansion and provides protection upon later reexposure to pathogen.	

The T lymphocytes activated by antigen presentation in the skin-associated lymph nodes then express skin-associated homing receptors (e.g., cutaneous lymphocyte antigen/CLA) that interact with adhesion molecules (E-selectin, P-selectin, VCAM-1, and ICAM-1) on cytokine-activated endothelial cells in the dermal vessels at the site of initial injury, thus providing a way for the activated lymphocytes to find their way back to the site of the pathogen. Once in the skin and after receipt of a renewed antigenic stimulus by the professional antigen-presenting cells, the sensitized T lymphocytes undergo clonal expansion, resulting in the generation of protective effector mechanisms. Most of the lymphocytes in the skin are T-helper lymphocytes, but various types of T lymphocytes and B lymphocytes contribute to adaptive immunity. Lymphocytes recognize pathogens (i.e., antigens) via cell surface receptors. The B lymphocytes have immunoglobulin molecules as the receptors for antigen, and upon activation, B lymphocytes secrete immunoglobulin, which provides defense against pathogens (often bacteria) in the extracellular spaces. In contrast, T lymphocytes have receptors that recognize foreign antigens expressed as peptide fragments bound to major histocompatibility complex (MHC) proteins (see [Chapter 5](#) for a review). One class of T lymphocyte expresses the CD8 molecule on the surface (i.e., CD8 T lymphocytes) and is responsible for cell-mediated immune responses. These CD8 T lymphocytes recognize peptide fragments (viral antigens and others) bound to MHC I. CD8 T lymphocytes kill some bacteria and parasites, and all viruses that replicate inside cells. These CD8 T lymphocytes recognize the antigen expressed on the cell surface, then kill the cell, and thus are also called “cytotoxic” T lymphocytes.

1120

1121

Another class of T lymphocytes express the CD4 molecule on their surface. This class of T lymphocyte is divided into two subclasses. One CD4 T-cell subset (T<sub>H</sub>1) recognizes peptide fragments (e.g., microbial antigen) bound to MHC II and activates macrophages, thus helping to control infection by intracellular bacteria, such as *Mycobacteria* spp. Upon phagocytosis, the lipoprotein on the surface of mycobacterial organisms binds surface receptors (including Toll-like receptors) on macrophages. This binding further stimulates macrophages, resulting in the secretion of macrophage IL-2, and production of nitric oxide within macrophages. Nitric oxide is toxic to the bacteria, and facilitates their killing. IL-2

## Pathologic Basis of Veterinary Disease, 4th Edition

stimulates CD4 T lymphocytes to release cytokines (interferon- $\gamma$  [IFN- $\gamma$ ] and TNF- $\alpha$ ), which activate and recruit more macrophages to the site of infection. The accumulating macrophages phagocytose and kill mycobacterial organisms and form granulomas. The other CD4 T-lymphocyte subset (T<sub>H</sub>2 [T-helper] cells) recognizes peptide bound to MHC II and activates B lymphocytes to secrete immunoglobulin, thus helping eliminate extracellular pathogens. Most antigens require an accompanying signal from helper T lymphocytes before they can stimulate B lymphocytes to proliferate and differentiate into plasma cells secreting antibody. Thus T lymphocytes are crucial to adaptive immunity by destroying pathogen-infected cells, by activating macrophages, and by activating B lymphocytes.

Down-regulation (i.e., a decrease in the number of or affinity for receptors on the cell surface) of the immune response has been less well studied. Typically the elimination of the stimulus results in resolution of the inflammatory or immune response. Also, some growth factors, particularly TGF- $\beta$ , and other cell products, such as prostaglandin E<sub>2</sub>, can have immunosuppressive functions leading to down-regulation of inflammatory and immune responses. Thus complex interactions between host cells, pathogens or other antigens, and inflammatory mediators of the adaptive immune system typically result in appropriate host defenses, the removal of the inciting pathogen, and the generation of differentiated memory lymphocytes through clonal expansion, allowing faster specific immune responses in future encounters with the offending antigen. However, impaired function of the adaptive immune system can lead to increased susceptibility to infection and to development of neoplasia. Similarly, uncontrolled inflammatory responses also can lead to chronic inflammation or autoreactive disorders, such as contact hypersensitivity, atopic dermatitis, or lupus erythematosus.

### 17.1.3.3 REGENERATION AND REPAIR

1121

Regeneration and repair also constitute a host defense mechanism to injury (Box 17-4). The details of tissue regeneration and repair are covered in Chapter 4, whereas the basic mechanisms involved in healing of cutaneous wounds will be summarized here. Two common types of cutaneous wounds will be used as examples, and these include wounds with opposed edges, such as surgical incisions, and larger wounds in which the edges cannot be opposed, such as broad ulcers, necrosis associated with deep burns, or large areas of trauma where portions of the skin have been lost (Fig. 17-8). Recall that regeneration and repair are a dynamic process involving multiple and overlapping stages. These stages include: (1) blood clotting and inflammation (12 to 24 hours after injury), (2) reepithelization, fibroplasia, and angiogenesis (3 to 7 days after injury), and (3) wound contraction and collagen production (1 to 2 weeks after injury).

1122

#### 17.1.3.3.1 Box 17-4 Host Defense Mechanisms against Injury: Regeneration and Repair

##### 17.1.3.3.1.1 BLOOD CLOTTING AND INFLAMMATION

Clot forms in vessel and wound space, provides matrix for cell migration, and dries to form scab over wound

Platelets and coagulation and complement cascade recruit inflammatory cells

Neutrophils and macrophages phagocytize pathogens and foreign debris

Macrophages secrete collagenase, facilitating tissue débridement, and transition between inflammation and repair

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.1.3.3.1.2 REEPITHELIZATION, FIBROPLASIA, AND ANGIOGENESIS

#### 17.1.3.3.1.2.1 Reepithelization

Epithelial cells produce proteases to dissect between viable and nonviable tissue, migrate and proliferate to cover wound, and reestablish basement membrane

#### 17.1.3.3.1.2.2 Fibroplasia

Fibroblasts produce proteolytic enzymes to provide path for migration, migrate and proliferate in wound site, and produce extracellular matrix to form connective tissue

#### 17.1.3.3.1.2.3 Angiogenesis

Endothelial cells form tubular structures that become blood vessels and reestablish blood flow

### 17.1.3.3.1.3 WOUND CONTRACTION AND COLLAGEN PRODUCTION

Fibroblasts produce collagen and contractile microfilaments that link to matrix

Newly formed collagen bundles link to each other and to collagen bundles at wound edge to contract the wound

Inflammation, edema, and vascularity gradually disappear

**Fig. 17-8 Schematic diagram of the steps in wound healing by first intention (left) and second intention (right).** Note large amounts of granulation tissue and wound contraction in healing by second intention. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 17.1.3.3.2 Healing of Wounds with Opposed Edges

The simplest healing involves the clean, uninfected, surgical incision in which the edges of the wound are closely opposed by sutures so the wound space is narrow (Fig. 17-8). Healing of these wounds is called primary union or healing by first intention. These wounds cause minimal necrosis of cells of the epidermis, dermis, and adnexa and minimal disruption of the basement membrane. Thus they heal quickly without significant architectural change, although a thin scar remains and the adnexa destroyed by the incision are permanently lost.

1122

1123

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The first stage of wound healing is blood clotting and inflammation and begins within the first 12 to 24 hours of injury. The process begins with blood vessel disruption, platelet aggregation, blood coagulation, and clot formation in the vessel and wound space. Dehydration of the surface of the clot forms the scab that covers the wound. The clot in the wound space provides the matrix for migration of inflammatory cells, endothelial cells, and fibroblasts. Platelet-derived factors and factors associated with the coagulation and complement cascades facilitate recruitment of inflammatory cells such as neutrophils and macrophages to phagocytose pathogens, foreign particles, and debris. Many of the cytokines and chemokines that govern inflammation in regeneration and repair are the same as those participating in inflammatory processes of other causes. Neutrophils, the first cells to arrive at the margins of the incision, phagocytose pathogens and debris, then either slough with desiccated tissue, are phagocytosed by macrophages, or undergo apoptosis. Macrophages replace neutrophils, secrete collagenase (facilitates tissue débridement), and release growth factors initiating the formation of granulation tissue.

The second stage of wound healing consists of reepithelialization, fibroplasia, and angiogenesis and is maximal between 3 and 7 days of injury. The process of reepithelialization begins within hours of injury from basal cell keratinocytes adjacent to the incision. In order for the basal cells to become mobile, they retract intercellular tonofilaments, dissolve desmosomes and hemidesmosomes, and form cytoplasmic actin filaments. In addition to mobility, within 24 to 48 hours from injury, there is mitosis of basal cells at the edges of the wound. The mitosis is induced by growth factors from epidermal cells, macrophages, and dermal parenchymal cells. Basal cells from both sides of the wound migrate along the cut edges of the dermis separating nonviable tissue from viable tissue by using the expression of various surface integrin receptors on viable cells and through the production of collagenase, which débrides dead tissue. The basal cells join at the midline of the wound, and as reepithelialization develops, the nonviable tissue above this newly united epidermis, is sloughed. Basal cells also produce extracellular matrix, such as fibronectin, to facilitate reestablishment of the basement membrane. The basal cells revert to a nonmigratory normal phenotype, form hemidesmosomes, and firmly reattach to the newly formed basement membrane, thus beginning the reestablishment of the epidermis over the wounded skin.

Fibroplasia and angiogenesis begin with the formation of granulation tissue, the term applied to a specialized type of tissue composed of proliferative fibroblasts and vascular endothelial cells produced in healing of soft tissue injury. Granulation tissue is the hallmark of healing and is named for its clinical appearance of soft pink to tan tissue with minute red foci consisting of capillaries (granules). However, it is the histologic appearance that is diagnostic, a lattice-work array of proliferative capillaries (angiogenesis) oriented perpendicular to proliferative fibroblasts (fibroplasia). The fibroblasts produce extracellular matrix, which is remodeled, ultimately resulting in scar formation (i.e., cicatrix formation).

The process of forming granulation tissue begins about 3 days after injury. Fibroplasia (fibrosis) is induced when cytokines (IL-1, TNF- $\alpha$ ) and growth factors (TGF- $\beta$ , PDGF, endothelial growth factor [EGF], FGF) from inflammatory cells (especially macrophages), platelets, and endothelial cells stimulate fibroblasts to proliferate, migrate, and ultimately produce extracellular matrix. As in reepithelialization, the ability of fibroblasts to migrate into the clot or provisional matrix requires alteration in expression of surface receptors and production of proteolytic enzymes to provide a path for migration. When fibroblasts have migrated into and filled the wound space, growth factors and cytokines (TGF- $\beta$ , PDGF, FGF, IL-1, IL-13) direct fibroblasts to switch from migration to protein (collagen) production, providing the structural protein that eventually contributes to wound strength. Collagen production begins by days 3 to 5 and persists for several weeks, depending on the size of the wound.

Concurrent with fibroblast migration into the wound space, angiogenesis, the formation of new blood vessels in an area of tissue injury, is also occurring (see [Chapter 2](#)). Angiogenesis develops from preexisting vessels and also from endothelial precursor cells (angioblast-like cells) from the bone marrow. Many growth factors play a role in angiogenesis, but vascular endothelial growth factor (VEGF) is considered to be the most important. In angiogenesis from preexisting vessels, macrophages and injured cells in the wound site release cytokines (such as FGF and VEGF), causing endothelial cells to release proteinases (e.g., procollagenase). The proteinases degrade components of the endothelial cell basement membrane. The disruption of the endothelial cell basement membrane removes the barrier otherwise confining endothelial cells, thereby permitting endothelial cells to migrate into the injured site in response to cytokines and growth factors released from injured or stimulated cells (e.g., FGF from macrophages, VEGF from keratinocytes, and heparin from mast cells). The migratory endothelial cells form tubes that express  $\alpha_v\beta_3$  integrin, facilitating endothelial cell adhesion and migration. The endothelial cells deposit provisional matrix of fibronectin and proteoglycans, and eventually form new basement membrane.

1123

1124

The growth factors continue to stimulate endothelial cell proliferation, ensuring a supply of endothelial cells for the extension of capillary tubes so that blood flow to the area of soft tissue injury can be reestablished. In angiogenesis from endothelial precursor cells, VEGF stimulates the mobilization of endothelial cell precursors from the bone marrow, and proliferation and differentiation of these cells at the site of injury; however, the mechanism whereby these cells are directed to the site of injury is unclear. Once at the site of injury, these endothelial cell precursors form a delicate capillary plexus that eventually links to existing capillaries, facilitating formation of a capillary network. The newly formed vessels, whether produced by sprouting from preexisting capillaries or from endothelial precursor cells, are provided structural support by pericytes (recruited by angiopoietin 1 interacting with Tie 2, an endothelial cell receptor) and smooth muscle cells (recruited by PDGF), and by production of extracellular matrix proteins (stimulated by TGF- $\beta$ ).

Angiogenesis is a well-regulated process. More than 20 molecules present in tissue act as angiogenesis inhibitors and modulate the reparative process. By the end of the second stage of wound healing, the incision is filled with granulation tissue, neovascularization is maximal, collagen fibrils bridge the incision, and reepithelialization has been completed. By day 7, the usual time to remove sutures, the tensile strength of the incision site is about 10% that of unwounded skin.

The third and final phase of wound repair involves collagen production and wound contraction. However, wound contraction principally affects large wounds that heal by second intention and is described later. Production of collagen and proliferation of fibroblasts (directed by cytokines, such as TGF- $\beta$ ) progress fairly rapidly in this phase of wound repair. In contrast, inflammation, edema, and increased vascularity disappear. The proliferation and maturation of endothelial cells, fibroblasts, and inflammatory cells that contribute to wound repair are dependent on complex feedback control mechanisms between cells, cytokines, enzymes, and the extracellular matrix microenvironment. This complex interaction has been called “dynamic reciprocity.” As the wound space is bridged by granulation tissue and fibroblasts produce collagen, the endothelial cells undergo apoptosis, thus reducing capillary numbers. Similarly, fibroblasts and macrophages also undergo apoptosis. The reduction of endothelial cells, fibroblasts, and inflammatory cells leads to formation of an acellular scar. By the third week of wound repair, the wound has about 20% the tensile strength of normal skin. Over the ensuing months, collagen production is reduced, but there is continued slow remodeling of the extracellular matrix leading to a healed wound that at maximum strength is only 70% to 80% that of unwounded skin.

### 17.1.3.3.3 Healing of Wounds with Separated Edges

Healing of wounds with separated edges (healing by second intention) occurs when there is more extensive loss of skin tissue. Healing by this process is more difficult and time consuming, and larger scars result and replace the cutaneous architecture. The principal differences between healing by primary intention and healing by second intention include: (1) in healing by second intention, inflammation is usually more extensive because there is more tissue damage that must be removed and secondary infection is more likely; (2) granulation tissue is more extensive because the wound has wider edges so there is a larger gap to fill; and (3) wound contraction occurs, reducing the size of the wound to a fraction of the original size (experimentally, it has been shown that large wounds in rabbits are reduced to 5% to 10% of their original size in about 6 weeks).

Wound contraction begins during the second week of healing when fibroblasts develop phenotypic characteristics of smooth muscle cells. These consist of cytoplasmic bundles of actin-containing microfilaments, and formation of cell-cell and cell-matrix linkages. Fibroblasts link to the extracellular fibronectin matrix and collagen matrix by fibronectin (e.g.,  $\alpha_5\beta_1$ ) and collagen (e.g.,  $\alpha_1\beta_1$ ,  $\alpha_2\beta_1$ ) receptors and to each other through direct adherens junctions. Also, newly synthesized collagen bundles form covalent cross-links with themselves and with collagen bundles at the wound edge. These linkages thus provide a conduit across the wound space so that the traction of fibroblasts on the matrix can contract the wound, substantially reducing its size and facilitating healing by second intention.

### 17.1.4 THE RESPONSES OF THE SKIN TO INJURY (A PRIMER TO HISTOLOGIC PATTERNS)

A number of “new” terms commonly used to classify diseases of the skin are used throughout this chapter. For convenience and to provide quick reference, these terms are listed at the end of this chapter in a glossary. Although there are many new terms to learn, it should be realized that the system of forming of these terms is similar to that used for other anatomic systems. Basically, prefixes and suffixes are added to word roots to create specific terms that define the pathology of the skin. For example, the prefix “epi” (meaning upon or above) combined with the word root “dermat(o)” (referring to skin) creates the word “epidermis,” which simply means the portion of the skin above the dermis. Likewise, the term *hypodermis* refers to the portion of the skin below the dermis, also called the subcutis or panniculus. Suffixes are used in the same way. For example, the suffix “itis” (meaning inflammation) combined with the word root “dermat(o)” forms the word “dermatitis,” which simply means inflammation of the skin. Similarly, terms referring to inflammation predominantly within the epidermis, follicles, or the panniculus are epidermitis, folliculitis, and panniculitis, respectively. The suffix “osis” refers to a disease process, often noninflammatory. Thus combining dermat(o) and osis forms the word “dermatosis,” which means any disease of the skin, especially one not characterized by inflammation. Dermatoses is the plural of dermatosis and thus means noninflammatory skin diseases.

1124

1125

Numerous endogenous and exogenous factors can potentially cause injury of the skin (Fig. 17-9). Determining a definitive diagnosis of a skin disorder depends on obtaining a complete history, including age, breed, and sex of the animal; conducting a thorough physical examination, paying particular attention to the distribution of skin lesions; and performing additional diagnostic tests, such as a complete blood count, serum chemistry panel, skin biopsy sampling, and microbiologic cultures. Results from cutaneous biopsy sampling are often useful and can be necessary to establish a definitive diagnosis for skin diseases. Although the skin has a limited range of responses to injury, the distribution and types of inflammatory cells in the lesion often represent a recognizable pattern that can be used to: (1) formulate a list of specific etiologic agents that could cause the lesion or (2) suggest categories of disease with similar lesions and a common pathogenesis.

## Pathologic Basis of Veterinary Disease, 4th Edition

Algorithms (i.e., a set of directions for accomplishing some task that has a recognizable end point) have been developed for the recognition of histopathologic patterns in veterinary dermatopathology (Table 17-3).

Recognition of patterns, both clinically and histologically, can facilitate differential diagnoses of skin disease (Table 17-4). Patterns of responses to injury are illustrated by changes in the epidermis, dermis, adnexa, and panniculus and are discussed in the following sections.

1125

1127

Table 17-3 Examples of Pattern Diagnosis in the Skin

Component of Skin	Reaction to Injury	Pattern	Disease Examples
Epidermis	Prominent hyperkeratosis	Hyperkeratotic diseases of the epidermis	Primary seborrhea Ichthyosis Vitamin A deficiency Callus
Dermis	Interface inflammation	Interface dermatitis	Lupus erythematosus Erythema multiforme
Follicle	Inflammation of the follicular lumen	Luminal folliculitis	Infection with staphylococci, Dermatophytes, <i>Demodex</i> sp.
Panniculus	Predominantly neutrophilic inflammation	Neutrophilic panniculitis	Abscess Feline pansteatitis (early)
A pattern consists of two parts: a component of the skin (e.g., epidermis) + a histologic reaction of that component to injury (e.g., hyperkeratosis) = pattern (hyperkeratotic diseases of the epidermis).			

**Fig. 17-9 Schematic diagram of the exogenous and endogenous factors that influence the skin.** A myriad of exogenous and endogenous factors influence the gross and microscopic appearance of the skin. Because the skin can respond to these factors in a limited number of ways, different skin disorders may have a similar appearance. Identification of the cause of a skin disorder therefore often requires not only histopathologic evaluation but also clinical history, including clinical lesion distribution and appearance. (Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

# Pathologic Basis of Veterinary Disease, 4th Edition

**Table 17-4 Differential Diagnoses of Selected Patterns That Can Be Recognized Clinically and Histologically**

Pattern	Pustules	Vesicles	Necrosis or ulceration (epidermal)	Scaling or other hyperkeratotic lesions* (epidermal)	Nodules ± draining tracts (dermal and pannicular)	Alopecia (adnexal)	Hypopigmentation or depigmentation (epidermal)
Disorders	Crusts (epidermal)	Bullae (epidermal) to subepidermal)					
	Superficial bacterial infection	Pemphigus vulgaris	Vasculitis/infarction	Primary seborrhea	Masses caused by deep infections with bacteria, fungi, algae, <i>Pythium</i> , migratory parasites (e.g., actinomycosis, feline leprosy, mycetoma, blastomycosis, pythiosis, habronemiasis abscesses)	Folliculitis: Infectious	Vitiligo
		Paraneoplastic	Chemical and thermal burns	Ichthyosis		Noninfectious	Uveodermatologic syndrome
	Pemphigus foliaceus and panepidermal pustular pemphigus	pemphigus	Superficial necrolytic dermatitis	Zinc responsive dermatosis		Postinflammatory and posttraumatic	Lupus erythematosus
		Lupus				Endocrine alopecia	Copper deficiency
	Dermatophilosis	erythematosus	Erythema multiforme	Sebaceous adenitis			
		Dermatomyositis					Alopecia areata (healing stage)
	Exudative epidermitis	Subepidermal	Stevens-Johnson syndrome	Ear margin seborrhea		Idiopathic flank alopecia	
	Subcorneal pustular dermatosis	bullous	Toxic epidermal necrolysis	Vitamin A responsive dermatosis	"Sterile" nodular inflammation (e.g., foreign body reactions, histiocytosis, sterile pyogranuloma, xanthoma, venomous bites, injection site reactions, eosinophilic granulomas)	Telogen effluvium	Inherited disorders (Chédiak-Higashi syndrome, Maltese and other coat color dilutions)
	Foot pads*	Drug reactions	Ergot/fescue grass toxicity	Feline exfoliative dermatosis and thymoma		Anagen defluxion	
	Pemphigus foliaceus	Chemical and thermal burns	Frostbite			Post clipping alopecia	
			Feline indolent ulcer	Callus		Follicular dysplasia	Waardenburg-like syndrome
	Superficial necrolytic dermatitis	Photosensitization				Congenital alopecia and hypotrichosis	Piebaldism
		Viral diseases	Feline ulcerative dermatosis syndrome	Cutaneous horn			Albinism
	Lupus erythematosus			Actinic dermatitis	Panniculitis/steatitis	Feline psychogenic alopecia	Cyclic hematopoiesis
			Vesicular cutaneous lupus erythematosus		Neoplasms		Contact with rubber
			Self-trauma			Poor nutrition with protein deficiency	
			Epitheliogenesis imperfecta			Feline paraneoplastic alopecia	

Some of these disorders could be placed in different patterns. For instance, disorders characterized by vesicles or bullae may develop into an ulcerative pattern after the vesicles or bullae rupture.

\* Hyperkeratotic disorders may also affect the nasal planum and footpads; see [Box 17-12](#).

## 17.1.4.1 RESPONSES OF THE EPIDERMIS TO INJURY

### 17.1.4.1.1 Alterations in Epidermal Growth or Differentiation

The basal cells (i.e., basal keratinocytes) in their postmitotic state migrate outward from the basal layer, eventually forming the cornified layers (stratum corneum) of the epidermis. In the normal epidermis,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

balance is established between the rate of proliferation of the basal cells (germinal cells) and the rate of loss of differentiated cells (squamous epithelial cells) from the surface, resulting in the constant thickness of the epidermis and each of the layers. The orderly proliferation, differentiation, and cornification of epidermal cells is regulated by cytokines (e.g., epidermal growth factor, fibroblast growth factors, insulin-like growth factors, interleukins, and tumor necrosis factor), hormones (e.g., cortisol and vitamin D<sub>3</sub>), and nutritional factors, such as protein, zinc, copper, fatty acids, and vitamin A and the B vitamins. The cytokines that regulate keratinocyte growth and differentiation are produced by a variety of cell types in the skin, including endothelial cells, leukocytes, fibroblasts, and keratinocytes. Thus keratinocytes also have a self-regulatory role (i.e., autocrine) in their growth and differentiation, and inflammatory cells, among others, can influence keratinocyte growth and differentiation.

17.1.4.1.1.1

### Disorders of cornification

Disorders of cornification (i.e., alterations in the formation of the stratum corneum) can be primary, such as in primary seborrhea, but more often are secondary to a variety of factors, such as inflammation, trauma, or metabolic or nutritional disorders. A disorder of cornification called hyperkeratosis is characterized by an increase in the thickness of the stratum corneum and occurs in two forms: orthokeratotic and parakeratotic hyperkeratosis. In orthokeratotic hyperkeratosis (also referred to as hyperkeratosis), squamous epithelial cells are anuclear, and in parakeratotic hyperkeratosis (also referred to as parakeratosis), the squamous epithelial cells have nuclei. Subtypes of hyperkeratosis include basket weave (exaggerated undulating pattern of layers the normal stratum corneum), compact (compacted layers of basket weave stratum corneum), and laminated (layers of stratum corneum that are more linear and less undulating). Both parakeratosis and hyperkeratosis are common nonspecific responses to chronic stimuli (e.g., superficial trauma, inflammation, or sun exposure) and also occur as primary lesions. For example, hyperkeratosis is a feature of the primary cornification disorder of the cocker spaniel (Fig. 17-10), ichthyosis, and vitamin A deficiency. Diffuse parakeratosis is a feature of zinc-responsive dermatosis and superficial necrolytic dermatopathy (hepatocutaneous syndrome) (Fig. 17-11). Hyperkeratosis and parakeratosis can be accompanied by alterations in the thickness of the granular cell layer (stratum granulosum). Generally, hyperkeratosis is associated with an increased thickness of the granular cell layer (hypergranulosis), and parakeratosis is associated with a decreased thickness of the granular cell layer (hypogranulosis).

**Fig. 17-10 Idiopathic seborrhea, skin, haired, dog.** **A**, Note the marked orthokeratotic hyperkeratosis (*H*). The stratum corneum within the hair follicles is increased in quantity, extends through the follicular opening to the external skin surface, and distends follicular openings (*arrows*), creating a papillomatous appearance in the epidermis. H&E stain. **B**, Hair is parted to reveal excessive scaling, the result of orthokeratotic hyperkeratosis. (*A and B*, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.1.4.1.1.2

#### Epidermal hyperplasia

Epidermal hyperplasia is an alteration in epidermal growth or differentiation characterized by an increase in the number of cells within the epidermis, most often within the stratum spinosum, and is also referred to as acanthosis. Hyperplasia is a response common to a variety of stimuli, often chronic, and occurs in a variety of types including regular, irregular, papillated, and pseudocarcinomatous (pseudoepitheliomatous) (Fig. 17-12). Some forms of epidermal hyperplasia (regular, irregular, and pseudocarcinomatous) can develop in sequence. In early stages of epidermal hyperplasia, the epidermal dermal interface is mildly undulating, but as the hyperplasia progresses, there often is an elongation of the rete ridges (ridges that extend into the dermis and interdigitate with dermal papillae) that can be regular or irregular. In regular epidermal hyperplasia, the rete ridges are approximately evenly sized and shaped, whereas in irregular epidermal hyperplasia, the rete ridges are less uniform. Pseudocarcinomatous hyperplasia is a chronic and late stage of epidermal hyperplasia that develops after milder forms (regular or irregular). It refers to marked hyperplasia of the epidermis, resulting in many branching and anastomosing epidermal ridges that deeply interdigitate with dermal collagen fibers. Mitotic figures can be numerous in proliferating basal cells, but in contrast to squamous cell carcinoma, the keratinocytes maintain normal polarity, are not atypical, and do not penetrate the basement membrane. Pseudocarcinomatous hyperplasia develops after chronic injury, as seen in skin damaged by long-term actinic radiation (i.e., repeated exposure to ultraviolet light) or at the edges of persistent, nonhealing ulcers. Psoriasiform epidermal hyperplasia is an exaggerated type of regular

1127

1128

## Pathologic Basis of Veterinary Disease, 4th Edition

epidermal hyperplasia in which the epidermis forms elongated rete ridges that are of similar length and width and that interdigitate with similarly elongated dermal papillae. This type of hyperplasia has very regular or uniform histologic appearance and is a feature of certain disease syndromes, such as psoriasiform lichenoid dermatitis of the springer spaniel and porcine juvenile pustular psoriasiform dermatitis (pityriasis rosea). Papillated epidermal hyperplasia is a unique form of epidermal hyperplasia in which fingerlike (papillary) projections of epidermis develop above the skin surface; it is a feature of some papillomas, hamartomas, and calluses.

**Fig. 17-11 Superficial necrolytic dermatitis, skin, dog. A,** Nuclei of the the thickened stratum corneum have been retained (parakeratotic hyperkeratosis [parakeratosis]). The epidermis has a trilaminar pattern created by three layers: (1) parakeratotic layer (*P*), (2) subparakeratotic edema/necrolytic layer (*N*), and (3) deep epidermal hyperplastic layer (*H*). The pathogenesis of superficial necrolytic dermatitis is not completely understood but is speculated that in most cases it is the result of an underlying systemic disease (such as severe liver disease or diabetes mellitus) that interferes with the normal nutrient metabolism needed to form a healthy epidermis. H&E stain. **B,** Footpad. Note the fissure (*arrow*) and crusts. The crusting is due largely to the parakeratosis. Secondary infections by bacteria, yeast, and fungi can also contribute to the formation of crusts by causing fluid, leukocytes, and other cellular debris to accumulate on the surface. (*A and B, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.*)

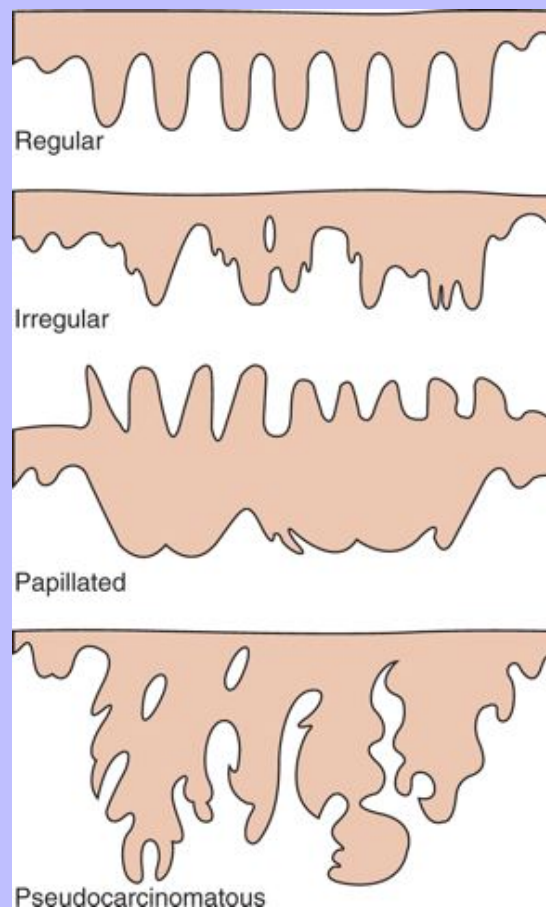

### Dyskeratosis

Dyskeratosis is an alteration in epidermal differentiation characterized by premature keratinization of cells in the viable layers of the epidermis. Dyskeratotic keratinocytes are shrunken, are separated from adjacent keratinocytes, and have a pyknotic nucleus and brightly eosinophilic cytoplasm because of the accumulation of keratin filaments. Dyskeratosis occurs when epidermal maturation is deranged, such as in zinc-responsive dermatosis. Dyskeratosis is also a feature of epidermal dysplasia, which is a premalignant change in actinic keratoses.

1128

1129

**Fig. 17-12 Schematic diagram of the patterns of epidermal hyperplasia.** Exaggerated regular epidermal hyperplasia is also called “psoriasiform” epidermal hyperplasia, named after the human condition of “psoriasis,” which is characterized by this type of epidermal hyperplasia. (*Adapted from Ackerman AB, Boer A, Bennis B et al, editors: Histologic diagnosis of inflammatory skin diseases, ed 3, New York, 2005, Ardor LRH.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.1.4.1.1.4

### Apoptosis

*Apoptosis* refers to programmed cell death. Apoptotic keratinocytes have the morphologic features of dyskeratotic cells. However, in apoptosis, the cytoplasmic eosinophilia is due to condensation of cytoplasmic organelles. Apoptotic cells are phagocytosed by adjacent keratinocytes. Phagocytosis before cellular disintegration prevents the development of an acute inflammatory response that would be elicited by the liberated cellular constituents. Thus the process of apoptosis is significantly different from that of necrosis, in which cell lysis releases cellular contents into the extracellular space and causes an inflammatory response. Apoptosis is seen with diseases such as lupus erythematosus and erythema multiforme ([Fig. 17-13](#)).

17.1.4.1.1.5

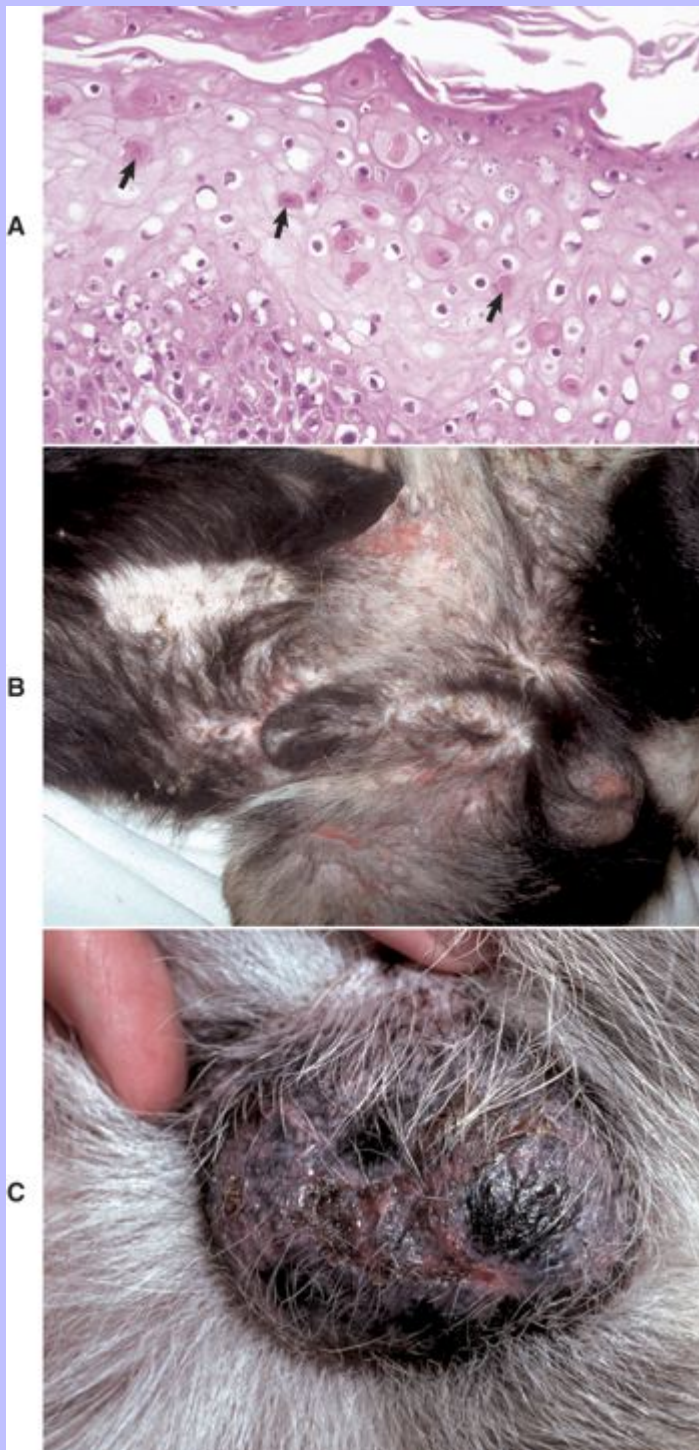

### Necrosis

*Necrosis* refers to the death of cells and is characterized by nuclear pyknosis (shrunken and dense nucleus), karyorrhexis (nuclear membrane rupture with fragmentation and release of contents), or karyolysis (complete dissolution of the nucleus with loss of chromatin material), organelle swelling, plasma membrane rupture, and release of cytoplasmic elements into the extracellular space accompanied by an acute inflammatory response. Causes of epidermal necrosis include physical injury (lacerations, thermal burns), chemical injury (irritant contact dermatitis), and injury as a result of ischemia and infarction (vasculitis, thromboembolism). Necrosis of the epidermis can result in erosion (loss of a superficial portion of the epidermis) or ulceration (loss of an area of the entire epidermis and portion of the dermis).

1129

1130

Fig. 17-13 **Erythema multiforme, skin, dog.** **A**, Apoptotic keratinocytes (*arrows*) are present in the cellular layers of the epidermis. The increased staining intensity of apoptotic keratinocytes is a result of condensation of cytoplasmic organelles and nuclei. H&E stain. **B**, Skin of abdomen, inguinal region, and scrotum. Note the circular and linear erosions. The clinical lesions resulting from apoptotic keratinocytes depend on the prevalence and location of the apoptotic cells in the epidermal strata. Numerous deeply located apoptotic keratinocytes can lead to loss of part of the epidermis, resulting in erosions that develop into ulcers. **C**, Scrotum erythema, ulceration, and crusting are present. Crusts form because the ulceration (injury) results in release of inflammatory mediators leading to the accumulation of fluid and cellular exudate that cover and dry on the ulcerated surface. Hargis, *DermatoDiagnostics*. **B**, Courtesy Clinical Dermatology Service, College of Veterinary Medicine, University of Florida. **C**, Courtesy Dr. Alexander Werner, Valley Veterinary Specialty Service.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.1.4.1.1.6

### Dysplasia

Dysplasia is defined as abnormal development. Classically, it refers to alteration in size, shape, and organization of adult cells (keratinocytes). Dysplasia is a stage of abnormal development that precedes the formation of a noninvasive (in situ) carcinoma. This is the stage of carcinoma that occurs before the abnormal epidermal cells penetrate the basement membrane. The histologic features include irregular stratification of keratinocytes, variation in cell and nuclear size, increase in number of mitoses, and large hyperchromatic nuclei.

17.1.4.1.1.7

### Atrophy

Atrophy is a decrease in the number and size of the cells within the epidermis and occurs as a consequence of sublethal cell injury. Cutaneous atrophy occurs in response to hormonal imbalances, such as hyperadrenocorticism in dogs and cats, partial ischemia, and in severe malnutrition.

17.1.4.1.2

### Alterations in Epidermal Fluid Balance and Cellular Adhesion

17.1.4.1.2.1

### Edema and intracellular fluid accumulation

*Edema* refers to fluid accumulation between cells. Intercellular edema of the epidermis is called spongiosis because as the intercellular space expands with fluid, the epidermis develops a “spongy” appearance ([Fig. 17-14](#)). The term “spongiosis” is used in other chapters of this book to describe responses to injury that are unique to other tissues or organ systems, and in those circumstances the term “spongiosis” will have different meanings. Severe intercellular edema of the epidermis results in the formation of spongiotic vesicles, which are variably sized vesicular spaces in the epidermis. The spongiotic vesicles often blend with intercellular spaces that are also widened, but to a lesser degree; thus intercellular bridges are often prominent between keratinocytes bordering spongiotic vesicles. Spongiosis is common in epidermal inflammation (epidermitis) caused by staphylococci or *Malassezia* sp.

Fig. 17-14 **Edema, skin, dog.** **A**, Intercellular epidermal edema. Note the appearance of “spines” between keratinocytes (*arrows*) caused by widening of the intercellular spaces by edema. The keratinocytes remain connected to each other via desmosomal attachment sites (Fig. 17-4). H&E stain. **B**, Acute allergic otitis, ear. Note erythema from dermal congestion (hyperemia) and the moist glistening surface of the skin from dermal and epidermal edema. (**A**, Courtesy Dr. Ann M. Hargis, *Dermato Diagnostics*. **B**, Courtesy Dr. David Duclos, *Animal Skin and Allergy Clinic*.)

Intracellular fluid accumulation results in cytoplasmic swelling of keratinocytes, and if the swelling is severe, the swollen keratinocytes can burst, forming microvesicles supported by the walls of the ruptured cells. This type of epidermal damage is termed “reticular degeneration.” Intracellular fluid accumulation limited to the basal layer of the epidermis is termed hydropic or vacuolar degeneration

## Pathologic Basis of Veterinary Disease, 4th Edition

and can result in the formation of intrabasilar vesicles. Hydropic degeneration is a consequence of damage to basal keratinocytes when the basal keratinocytes cannot maintain normal homeostasis, and fluid accumulates within the cells (Fig. 17-15). Examples of diseases commonly resulting in hydropic degeneration include lupus erythematosus, dermatomyositis, and drug eruptions. Ballooning degeneration, a form of intracellular fluid accumulation of keratinocytes in more superficial layers of the epidermis, such as the stratum spinosum, is characterized by swollen cells losing their intercellular attachments. This type of degeneration can result in the formation of a fluid-filled vesicle. Viruses that infect cells of the epidermis, such as the pox and parapox viruses, can cause lysis of cytoplasmic keratin and a buildup of excessive fluid, resulting in ballooning degeneration (see Pathologic Reactions of the Entire Cutaneous Unit).

1130

1131

**Fig. 17-15 Hydropic degeneration, skin, dog. A,** Note vacuolization of the cells of the basal layer. In this photomicrograph, the vacuolated basal cells resemble clefts (*arrows*) between the epidermis and dermis. Lymphocytes are also present in the superficial dermis and lower layers of the epidermis, obscuring the junction between the epidermis and dermis. H&E stain. **B,** Dermatomyositis, periocular. Erythema, depigmentation, erosion, and crusting are the result of injury to basal cells. The vacuolar degeneration of basal cells weakens the epidermal dermal attachment and results in formation of vesicles, erosions, and ulcers. In addition, inflammatory mediators are released, resulting in fluid and cellular exudate, which dry on the surface and form crusts. (**A** and **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

## Pathologic Basis of Veterinary Disease, 4th Edition

17.1.4.1.2.2

### Acantholysis

Acantholysis is the disruption of intercellular junctions (desmosomes) between keratinocytes of the epidermis. The process is initiated by damage to transmembrane glycoproteins belonging to the cadherin family of adhesion molecules, and leads to splitting of the extracellular core of the desmosomes. Subsequently the desmosomal plaques dissolve and intermediate filaments retract to the perinuclear region of the keratinocytes. Acantholysis occurs with immune-mediated injury, as seen in pemphigus (type II cytotoxic hypersensitivity) or with neutrophilic enzymatic destruction, as seen in superficial pyoderma or uncommonly with some *Trichophyton* sp. infections. The microscopic lesions vary with the location of acantholysis within the various layers of the epidermis. In pemphigus foliaceus, acantholysis occurs in the subcorneal epidermis, resulting in release of free-floating keratinocytes in subcorneal vesicles and pustules (Fig. 17-16). In pemphigus vulgaris, acantholysis occurs in the epidermis, just above the basal layer, resulting in the separation of the upper epidermis from the basal cells (which are often referred to as “a row of tombstones”) attached to the basal lamina (Fig. 17-17). Fluid accumulating between the separated layers of the epidermis forms vesicles of varied sizes and shapes.

17.1.4.1.2.3

### Vesicles

Vesicles are fluid-filled cavities within or beneath the epidermis (Fig. 17-18). If the cavity is less than 1 cm in diameter, it is called a vesicle; if it is greater than 1 cm in diameter, it is called a bulla (pl. bullae). Vesicles can develop in any layer of the epidermis or beneath the epidermis and can form as the result of acantholysis, epidermal or dermal edema, degeneration of basal cells and keratinocytes, or other processes, such as frictional trauma and burns that cause a lack of cohesion between the epidermal cells or between the epidermis and dermis, resulting in the accumulation of fluid within a cavity. The location of vesicles or bullae within the layers of the epidermis is suggestive of certain diseases. For instance, intraepidermal vesicles can occur in viral infections, subcorneal vesicles in pemphigus foliaceus, suprabasilar vesicles in pemphigus vulgaris (Fig. 17-17), and subepidermal vesicles in bullous pemphigoid or thermal burns (Fig. 17-19).

17.1.4.1.3

### Inflammatory Lesions of the Epidermis

Acute inflammation of the epidermis actually begins in the dermis with active hyperemia, edema, and migration of leukocytes, often neutrophils (see inflammatory disorders of the dermis section). The edema fluid arises from dilated venules and can move intercellularly through the epidermis, widening the intercellular spaces and causing spongiosis. In thermal burns of the skin, larger quantities of fluid accumulate within or below the epidermis forming vesicles; the fluid reaching the epidermal surface dries to form a largely acellular crust. The leukocytes (often neutrophils in acute inflammation) migrate from the superficial dermal vessels, through the superficial dermis, and into the intercellular spaces of the deep and then superficial layers of the epidermis. The aggregation of migrating leukocytes in the epidermis is termed “exocytosis.” Exocytosis of leukocytes is common in inflammation and is usually accompanied by spongiosis. If the inflammation progresses, the migrating leukocytes form pustules within the epidermis or the stratum corneum. Pustules usually dry rapidly and become crusts (Fig. 17-20). The type of leukocyte recruited into the epidermis is influenced by complex interactions of cytokines involved in the pathogenesis of the disease and can be useful in classifying and ultimately diagnosing the disease. For instance, intraepidermal eosinophils can be seen in association with ectoparasite bites. Lymphocytic infiltrates into the epidermis are often seen with immune-mediated

1131

1132

1132

1133

## **Pathologic Basis of Veterinary Disease, 4th Edition**

---

diseases such as lupus erythematosus. Malignant lymphoma affecting the epidermis is also characterized by intraepidermal lymphocytes. Erythrocytes can also be present in the epidermis, usually associated with trauma, or circulatory disturbances, such as marked vasodilation and vasculitis.

Fig. 17-16 **Pemphigus foliaceus, skin.** **A**, Horse. The subcorneal pustule contains neutrophils and acantholytic cells (*arrows*), which are epidermal cells separated from each other as a result of the loss of desmosomal attachments. In pemphigus foliaceus, the pustule is located in the superficial epidermis, resulting in clinical lesions that are superficial (pustules that can rupture to form erosions and crusts). The roof of the pustule is the stratum corneum, and the base of the pustule is the stratum spinosum. Forceful clipping or scrubbing the surface of the pustule can lead to rupture and thus can make the sample nondiagnostic. H&E stain. **B**, Inguinal region, dog. Multiple pustules (circumscribed accumulations of pus in the epidermis visible as irregularly ovoid, slightly elevated tan areas) are present in the sparsely haired skin of the inguinal region. The skin within the circle has been injected with local anesthetic in preparation for biopsy sampling. **C**, Face, dog. Erythema, alopecia, focal erosion, crusting, and depigmentation are present on medial surface of the pinnae, periocular skin, and dorsum of the muzzle and the nasal planum. Crusts develop as the result of upward growth of the epidermis and disruption of pustules. Erosions develop as the result of loss of stratum corneum and pustular exudate, which exposes the stratum spinosum. Depigmentation can result from inflammation and damage to pigment containing epidermal cells. **D**, Foot pad, dog (same dog as in [Fig. 17-16, C](#)). Erosions (*arrows*), depigmentation, and crusts are present. (**A**, Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida. **B**, Courtesy Dr. David Duclos, Animal Skin and Allergy Clinic. **C** and **D**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Fig. 17-17 **Pemphigus vulgaris, skin, dog.** **A**, Suprabasilar clefting has left a row of basal cells (*arrows*) attached to the dermis. The single row of basal cells is fragile and easily damaged leading to formation of ulcers, with subsequent fluid loss and secondary bacterial infection. H&E stain. **B**, Leg. Note the erythema and large confluent areas of ulceration. In contrast to pemphigus foliaceus (more commonly characterized by erosions and crusts), pemphigus vulgaris is characterized by ulcers because the acantholysis in pemphigus vulgaris occurs deeper in the epidermis (in the cells of the lower epidermis). Vesicles are not frequently seen as they rapidly progress to ulcers, the more common clinical lesion. (**A**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics. **B**, Courtesy Dr. Allan Mundell, Animal Dermatology Service.)

**Fig. 17-18 Thermal burn, full thickness (third degree) skin, dog.** **A,** There is necrosis of the epidermis (*arrow*), follicular epithelium, and dermis. Because of increased capillary permeability, fluid has accumulated between the dermis and epidermis, forming vesicles (*V*). H&E stain. **B,** The dry necrotic skin is the site of the burn (*arrow*). (*A and B, Courtesy Blackwell Publishing.*)

17.1.4.1.3.1

### Pustules

Pustules (microabscesses) are accumulations of inflammatory cells (pus) within the epidermis (Fig. 17-16). Epidermal pustules vary in inflammatory cell content and location in the epidermis, depending on the pathogenesis of the disease. The pustules of superficial bacterial infections generally contain degenerate neutrophils and coccoid bacteria and are often located beneath the stratum corneum (subcorneal). In ectoparasitic hypersensitivity, pemphigus foliaceus, and feline eosinophilic plaque, the pustules can be filled with eosinophils. Small pustules containing neoplastic lymphocytes (Pautrier's microabscesses) are present in epitheliotropic lymphoma.

1133

1134

**Fig. 17-19 Schematic diagram of the sites of vesicle formation in the skin.** **A**, In a subcorneal vesicle, the stratum corneum forms the roof of the vesicle (as in impetigo or pemphigus foliaceus). **B**, In a suprabasal vesicle, a portion of the epidermis (stratum spinosum) forms the roof (as in pemphigus vulgaris). **C**, In a subepidermal vesicle, the entire epidermis separates from the dermis and forms the roof (as in bullous pemphigoid). (**A**, **B**, and **C**, From Cotran RS, Kumar V, Collins T, Robbins SL: Robbins pathologic basis of disease, ed 6, Philadelphia, 1999, Saunders.)

**Fig. 17-20 Schematic diagram of the inflammatory patterns of the epidermis.** **A**, Leukocytes (black dots) migrate from the perivascular dermis into the epidermis, a process called exocytosis. **B**, Leukocytes migrate into the epidermis and accumulate to form a pustule. **C**, The pustule dries to form a crust. ---

17.1.4.1.3.2

### Crusts

Crusts are composed of dried fluid and cellular debris (i.e., dried exudates) located on the epidermal surface; thus crusts are indicative of a previous exudative process. Crusts are not specifically diagnostic but can hold the key to diagnosis in some diseases. For example, in dermatophilosis, the most diagnostic portion of the skin is the crust, which is multilaminated and contains the gram-positive, branching coccoid organism *Dermatophilus congolensis*. Similarly, crusts formed through aging of pustules in pemphigus foliaceus are multilaminated and frequently contain numerous acantholytic cells. Crusts can also contain hair shafts infected with spores and hyphae of dermatophytes.

17.1.4.1.4

### Alterations in Epidermal Pigmentation

Pigmentary alterations include hyperpigmentation, hypopigmentation, and pigmentary incontinence. Melanin is produced by melanocytes located in the basal and lower spinous layers of the epidermis, in the external root sheath and hair matrix of follicles, and perivascularly in the dermis. Melanocytes have surface receptors for hormones, such as melanocyte-stimulating hormone, and these hormones regulate melanogenesis. Other factors that influence the amount of melanin pigment in skin and hair are genes, age, temperature, and inflammation.

1134

1135

17.1.4.1.4.1

#### Hyperpigmentation

Hyperpigmentation results from an increased production of melanin from existing melanocytes or an increase in the number of melanocytes. An example of hyperpigmentation due to an increased number of melanocytes is a lentigo, a rare localized nonneoplastic proliferation of melanocytes confined to the epidermis and resulting in formation of a black macular circumscribed lesion that is usually less than 1 cm in diameter. Most hyperpigmentation of the epidermis results from increased production of melanin from existing melanocytes. Possible mechanisms of increased melanin production include increases in the rate of production of melanosomes (i.e., granules within melanocytes that contain tyrosinase and synthesize melanin), in melanosome size, in rates of melanosome transfer to keratinocytes and increased survival of melanosomes in keratinocytes. Examples of epidermal hyperpigmentation by increased production of melanin include chronic inflammatory diseases (most common cause), such as chronic allergic dermatitis, and endocrine dermatoses, such as hyperadrenocorticism. Hyperpigmentation secondary to inflammation is thought to result from release of melanocyte-stimulating factors from keratinocytes. It is thought that these factors are present in normal epidermis, but that their level or activity is increased in response to stimulation or keratinocyte stress.

17.1.4.1.4.2

#### Hypopigmentation

Hypopigmentation can be congenital or hereditary and develops because of a lack of melanocytes, failure of melanocytes to produce melanin, or failure of transfer of melanin to epidermal cells. Hypopigmentation can also be acquired via a loss of existing melanin or melanocytes (depigmentation). Because copper is a component of tyrosinase, production of melanin pigment is dependent on copper, and copper deficiency can result in reduced pigmentation.

17.1.4.1.4.3

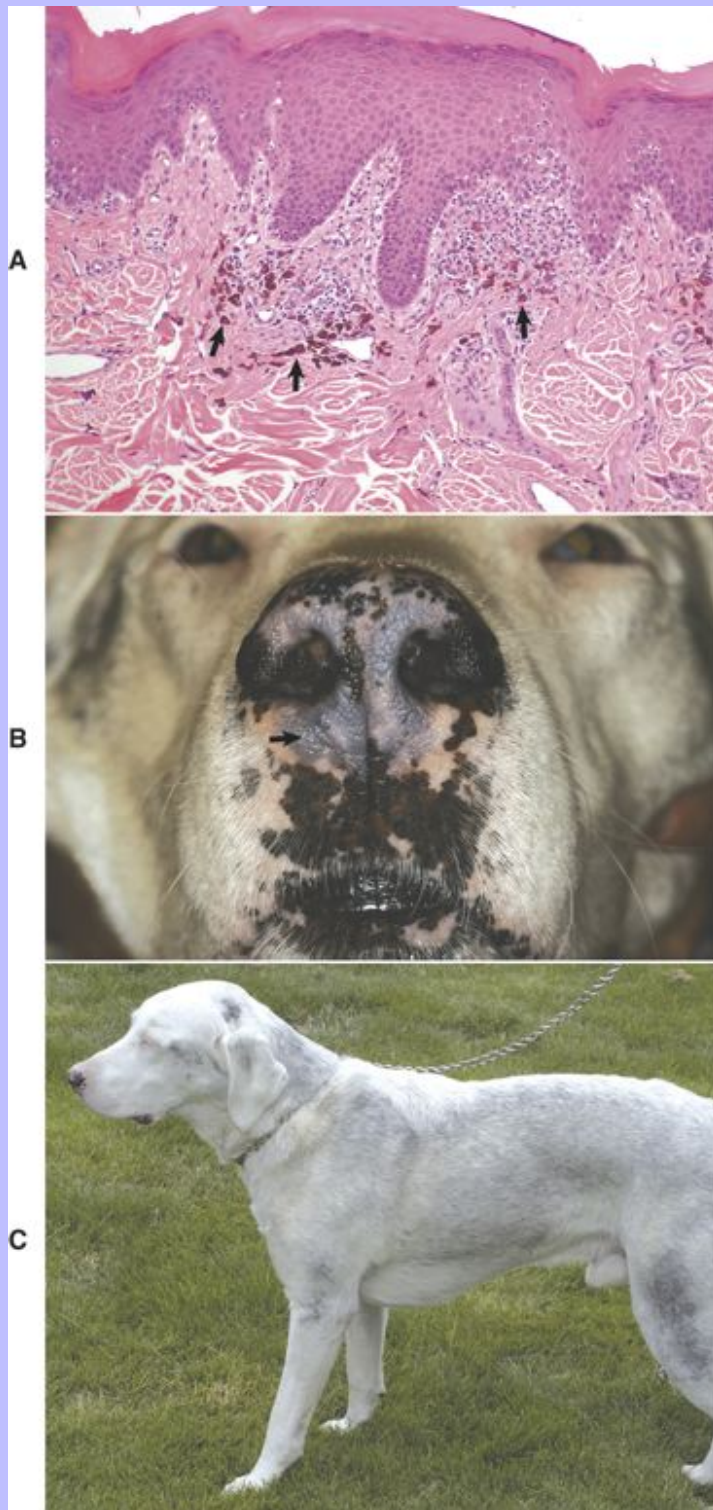

### Pigmentary incontinence

*Pigmentary incontinence* refers to the loss of melanin pigment from the basal layer of the epidermis caused by damage to the cells of the basal layer and the accumulation of the pigment in macrophages in the upper dermis. Pigmentary incontinence can be a nonspecific lesion associated with inflammation; however, it is also seen with diseases that specifically damage basal cells or melanocytes, such as lupus erythematosus or vitiligo. Leukotrichia ([Fig. 17-21](#)) and leukoderma refer to decreased pigmentation of hair and skin, respectively.

1135

1136

**Fig. 17-21 Leukoderma, skin, dog. A,** Injury to the epidermal pigment containing cells (predominantly melanocytes) has caused loss of melanin pigment in the epidermis (leukoderma). The pigment from the damaged melanocytes has been phagocytosed by dermal macrophages (pigmentary incontinence) (*arrows*). Mild to moderate lymphocytic inflammation is present along the epidermal dermal interface. H&E stain. **B,** Nose and lips. Areas of the normally black skin of the planum nasale and lips have been partially (*bluish-gray*) or totally (*pink*) depigmented. The bluish-gray areas are in the process of becoming depigmented. Biopsy samples should be collected from the bluish-gray areas (*arrow*) to identify active inflammation and diagnostic lesions. Biopsy samples from black skin or from already totally depigmented skin will likely only show normal appearing black or nonpigmented skin, respectively, with no evidence of inflammation. **C,** Leukotrichia, body. This dog is the same one depicted in [Fig. 17-21, B](#). He is a black Labrador retriever mix. More than 90% of the black hair coat became white (leukotrichia). Biopsy samples from white-haired areas may be normal because the inflammatory event that caused the pigment loss is likely gone by the time nonpigmented hair shafts emerge from the hair follicles. (**A**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics. **B** and **C**, Courtesy Dr. David Duclos, Animal Skin and Allergy Clinic.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.1.4.2 RESPONSES OF THE DERMIS TO INJURY

#### 17.1.4.2.1 Alterations in Growth, Development, or Tissue Maintenance

##### 17.1.4.2.1.1 Dermal atrophy

Dermal atrophy results from a decrease in the quantity of collagen fibrils and fibroblasts in the dermis and leads to a decrease in the thickness of the dermis noted clinically by thin, translucent skin with more visible vasculature. The principal causes of dermal atrophy in domestic animals are catabolic diseases associated with protein degradation, such as hyperadrenocorticism (particularly in dogs and cats), and starvation. In cats with hyperadrenocorticism, collagen loss is sufficient to increase fragility of the skin, which tears with normal handling. Severe dermal atrophy can also be caused by repeated topical application of glucocorticoids.

**Fig. 17-22 Granulation tissue, skin, horse.** **A**, Note vertically oriented capillaries (C) and horizontally oriented fibroblasts and a few collagen fibers providing a “lattice-work” appearance to the granulation tissue. **B**, Leg. Note ulcerated area filled with granulation tissue. **C**, Exuberant granulation tissue, leg. Granulation tissue is a normal component of wound healing. However, excessive or exuberant granulation tissue can develop as a pathologic process. This condition occurs especially in horses, when an ulcer fails to become reepithelialized. Although this process is commonly called “exuberant granulation tissue,” at the stage depicted in this photograph, most of the granulation tissue has been converted to fibrous connective tissue. (**A**, **B**, and **C**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.1.4.2.1.2

### Fibrosis

Fibrosis (fibroplasia) develops in response to various injuries, particularly ulceration of the epidermis. It consists of proliferation of fibroblasts and newly formed collagen fibrils (extracellular matrix). In the early stage of fibroplasia called “granulation tissue,” the long axis of the fibroblasts and collagen fibrils are parallel to the surface of the skin and are oriented perpendicular to vertically aligned proliferative vessels. Clinically the capillaries are seen on the surface as minute red dots that create a “granular” appearance, thus the name “granulation tissue.” Microscopically the orientation pattern provides a “lattice-work” appearance to the tissue (Fig. 17-22). Fibrosis refers to the gradual deposition and maturation of collagen to form a scar. During fibrosis, collagen production increases and fibroblast and capillary numbers decrease, resulting in less cellular dense collagen oriented in thick hyaline bundles in parallel arrangement (e.g., a scar), which grossly appear white and glistening.

1136

1137

17.1.4.2.1.3

### Collagen dysplasia

Collagen dysplasia is generally an inherited abnormality of collagen that results in decreased tensile strength and an increased ability of the skin to stretch beyond normal limits. Because the tensile strength is reduced, even minor trauma can cause the skin to tear. Healing results in formation of scars. Microscopic features vary among the different types of collagen dysplasia disorders, and in some the skin has no microscopic alterations. Collagen bundles can vary in size and shape and consist of tangled fibers with an abnormal organizational pattern.

17.1.4.2.1.4

### Solar elastosis

Solar elastosis is caused by chronic exposure of the skin to the ultraviolet spectrum of sunlight. Sunlight consists of visible, ultraviolet (UV), and infrared light rays. The portion of the UV light most damaging to the skin is ultraviolet B (UVB) and is in the range of 290 to 320 nm. The amount of light reaching the skin is dependent on a variety of environmental and host factors that can greatly influence the geographic incidence and anatomic locations of solar damage. Environmental factors include quantity of ozone, smog, and cloud cover that tend to absorb and scatter some of the UV rays. Altitude and latitude are also very important. The atmosphere at high altitude is thinner, so there is less oxygen and particulate matter to absorb and scatter the UV rays. Latitude is also critically important. It has been estimated that the incidence of sunlight-induced cancer in human beings doubles for every 265 miles closer to the equator that human beings reside. At high latitudes, the path of sunlight through the ozone layer is longer than at lower latitudes, so more of the harmful UV light is absorbed by the ozone. The path of sunlight through the ozone layer is also one of the reasons that sunlight has more damaging UV rays in summer months and at midday. Increased wind velocity has also been shown to have an enhancing influence on damaging effects of UV light on the skin. Local environmental factors can influence the quantity of UV light reaching an animal's skin. Such factors include availability of shelter from sunlight in the form of trees, shade panels, or indoor housing, and color of the ground material (lightly colored sand) that can increase exposure to UV light through reflection. Host factors include quantity of hair, degree of pigmentation, thickness of stratum corneum, and other difficult to define genetic factors. Therefore solar damage is more prevalent in high altitude, low latitude parts of the world and in animals residing outside for long periods of time. Lesions generally develop in poorly haired and lightly pigmented sites. Solar elastosis consists of increased numbers of thick, interwoven, basophilic elastic fibers in the superficial dermis. In the nonpigmented abdominal skin of dogs, solar elastosis may develop intermixed with or below a linear

## Pathologic Basis of Veterinary Disease, 4th Edition

---

band of scarring parallel to the epidermal surface. In human beings, studies have revealed that the solar-damaged elastic tissue is newly formed as a result of altered function of fibroblasts, not a degeneration product of preexisting elastic fibers. Solar elastosis is less prominent in the skin of domestic animals than in human beings but is often prominent in lightly pigmented, poorly haired sun-exposed skin and eyelids of horses and in the lower eyelids of Hereford cattle residing in sunny locations.

### 17.1.4.2.2 Degenerative Collagen Disorders of the Dermis

The term “collagen degeneration” has been used to refer to an altered histologic appearance of collagen fibers in hematoxylin and eosin (H&E) stained sections, whereby there is brightly eosinophilic granular to amorphous material bordering the fibers and somewhat obscuring the fiber detail. The collagen fibers and bordering eosinophilic material have also been referred to as “flame figures” due in part to the irregular, sometimes radiating, edges and brightly eosinophilic staining intensity. Electron microscopic studies in cats and human beings indicate that the collagen fibers can be disrupted, but they are not “degenerate.” Instead, the brightly eosinophilic granular and amorphous material consists of aggregates of many eosinophils and eosinophil granules that border slightly disrupted but otherwise normal collagen fibers. These flame figures are seen in conditions in which eosinophils are prominent, including in reactions to insect bites, mast cell tumors, and eosinophilic granulomas (collagenolytic granulomas) (Fig. 17-23). Collagen lysis refers to dissolution of collagen fibrils morphologically consisting of amorphous, lightly eosinophilic material lacking fibrillar detail. Collagen lysis is likely a secondary event caused by proteolytic enzymes released by a variety of cells, including eosinophils (collagenase) and neutrophils (collagenolytic proteinase, collagenase).

### 17.1.4.2.3 Disorders Characterized by Abnormal Deposits in the Dermis

#### 17.1.4.2.3.1 Amyloid

Amyloid is an abnormal proteinaceous substance that can be deposited in the skin as a result of a primary abnormality of immunocytes (primary amyloidosis), in which case the amyloid is derived from components of immunoglobulin light chains (AL amyloid), or as a result of chronic inflammatory conditions (secondary amyloidosis), in which case the amyloid is derived from serum amyloid-associated protein (SAA protein), an acute phase reactant produced by the body in response to inflammation. Cutaneous deposition of amyloid is rare but is seen in dogs and horses. Cutaneous deposition of amyloid in dogs can be triggered by a monoclonal gammopathy or plasma cell tumors (AL amyloid) or by dermatomyositis (SAA protein). Clinical lesions reflect the triggering disease. In horses, cutaneous amyloidosis is most often due to deposits of amyloid derived from SAA protein, but underlying inflammatory conditions are not usually identified. Clinical lesions vary from papules and plaques to nodules that usually are covered by a normal hair coat. Similar nodules can also develop in the respiratory mucosa and regional lymph nodes. Histologic lesions include nodular to diffuse granulomatous dermatitis and panniculitis with deposition of amyloid, an eosinophilic hyaline material.

1137

1138

Fig. 17-23 C, Upper lip. Bilateral ulcers are present on the upper lips, but the ulcer on the right side of the photograph is more extensive (arrow). (A, B, and C, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.1.4.2.3.2

#### Mucin

Mucin (glycosaminoglycan [GAG]), a normal component of the ground substance of the dermis, consists of protein bound to hyaluronic acid and can be deposited in increased quantity in focal areas or diffusely. Because hyaluronic acid has a great affinity for binding water, the skin in cases of mucin deposition (mucinosis) has a thick, puffy appearance. In cases of severe mucinosis, the skin, when pricked with a needle, can exude mucin (a stringy fluid material). In histologic sections, much of the water is lost and mucin appears as fine amphophilic granules or fibrils that separate dermal collagen. Examples of disorders with dermal mucin deposition are termed myxedema in hypothyroidism and mucinosis in the Chinese Shar-Pei dog.

### 17.1.4.2.3.3

#### Calcium deposits

Calcium deposits are deposits of insoluble calcium salts within cutaneous tissue and are referred to as mineralization or calcification. Mineralization can occur in three basic forms: (1) dystrophic, (2) metastatic, and (3) idiopathic. Dystrophic mineralization occurs as a result of injury or degeneration of skin components. Mechanisms leading to calcium deposition in dystrophic mineralization are complex and involve reduced pH of injured tissue, mitochondrial concentration of calcium and phosphorus, and the influx of calcium into injured cells. Examples include deposition of mineral in granulomas and calcinosis cutis seen in some cases of hyperadrenocorticism. In metastatic mineralization, the calcium deposits develop in association with abnormal metabolism of calcium, phosphorus, and vitamin D.

## Pathologic Basis of Veterinary Disease, 4th Edition

Mechanisms thought to participate in mineral deposition are loss of mineralization inhibitors, changing of ions into a solid phase, and phosphate ion initiation of crystal formation. Examples include deposition of calcium salts in soft tissues in chronic renal disease and in poisoning with cholecalciferol (vitamin D<sub>3</sub>). The causes of idiopathic mineralization are not known. Mineralization can affect individual or groups of collagen fibers, resulting in increased basophilia and fragmentation of fibers in H&E stained sections. Calcium can also be deposited as amorphous nodular aggregates (calcinosis circumscripta). Calcium deposits can elicit a granulomatous inflammatory response, a foreign-body reaction to the deposits.

1138

1139

17.1.4.2.4

### Inflammatory Disorders of the Dermis

Dermatitis is inflammation of the dermis. Acute dermatitis begins with active hyperemia (increased blood flow), edema, and migration of leukocytes and results from release of cytokines and other mediators of acute inflammation (see [Chapter 3](#)). Active hyperemia is due to vasodilation of arterioles, which causes increased blood flow at reduced velocity to capillary beds and postcapillary venules. Edema is due to increased vascular permeability. Fluid leaves vessels mostly through widened interendothelial cell junctions. With a mild increase in vascular permeability, the edema fluid is clear (serous) because there are very few plasma proteins in the fluid. With increasing vascular permeability or endothelial cell injury, larger protein molecules such as fibrinogen escape from vessels, and the edema fluid becomes more eosinophilic and amorphous to fibrillar (fibrinous). The next step in acute dermatitis is migration of leukocytes from vessels into the perivascular dermis. The slowing of the blood flow and the endothelial cell expression of adhesion molecules that bind circulating leukocytes permit the migration of leukocytes in acute inflammation. The slowing of the blood flow allows leukocytes to move from the center of the vessel, where blood flow is fastest, to the margin, where they contact and attach to the activated endothelial cells.

After attaching to activated endothelial cells, leukocytes migrate between the endothelial cells into the perivascular dermis. The type of leukocyte that migrates and the sequence of cellular influx depend on activation of different adhesion molecules and chemotactic factors in the different phases of inflammation. In many types of acute inflammation, neutrophils are one of the first cells to arrive. Neutrophils predominate in the first 6 to 24 hours of injury and are generally replaced by macrophages in 24 to 48 hours. There are exceptions to this sequence of cellular exudation. For instance, in reactions mediated by immunoglobulin E (IgE) cross-linking, such as type I hypersensitivity responses, mast cells (located in the perivascular dermis) are stimulated to release contents of granules (occurs in seconds), and synthesize and release inflammatory mediators (prostaglandins, leukotrienes, cytokines) resulting in the influx of eosinophils, basophils, CD4-T<sub>H</sub>2 lymphocytes, and macrophages. Mast cell degranulation and T<sub>H</sub>2 lymphocyte activation cause eosinophils to accumulate in large numbers. Thus eosinophils often comprise the majority of leukocytes in inflammatory reactions against parasites and other allergic reactions. Also in type IV hypersensitivity reactions mediated by sensitized T lymphocytes (delayed-type hypersensitivity), CD4 lymphocytes (T<sub>H</sub>2 [helper]) are present first and constitute a majority of the perivascular inflammatory cells in fully developed lesions.

Acute dermatitis typically results in one of four outcomes. First, there can be complete resolution, which occurs when the inciting stimulus has short duration and there is little tissue damage that is completely repaired. Second, an abscess can form, which occurs with pus-producing (pyogenic) bacterial infections. Third, healing occurs by replacement of the injured area by fibrous connective tissue (e.g., scarring), which occurs when there is significant tissue destruction (such as a deep burn) in which the parenchymal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

tissues are lost and thus cannot regenerate. Fourth, there is progression of acute dermatitis to chronic dermatitis.

Chronic dermatitis is inflammation of the skin that lasts weeks or months. Histologic features of chronic dermatitis include: accumulation of macrophages, lymphocytes, and plasma cells; tissue destruction in part caused by the inflammatory cells; and a reparative host response of fibrosis and angiogenesis. Chronic dermatitis is usually caused by persistent infections often associated with delayed hypersensitivity and the formation of granulomas (e.g., *Mycobacteria* sp.), presence of foreign material in the skin (e.g., embedded suture), or autoimmune reactions in which self-antigens provoke an ongoing immunologic inflammatory response against host tissue (e.g., lupus erythematosus). Macrophages are a key cell in chronic dermatitis. They arise from monocytes in the peripheral blood and mature to macrophages whose primary function is phagocytosis. Macrophages also become activated by a variety of chemical mediators, including the cytokine IFN- $\gamma$  secreted by sensitized T lymphocytes. When activated, macrophages also secrete many mediators of tissue injury (toxic oxygen metabolites, proteases, coagulation factors) and fibrosis (growth factors, angiogenesis factors, collagenases) that contribute to chronic inflammation. The presence of lymphocytes and plasma cells in chronic inflammation is indicative of a host immune response.

The inflammatory milieu in the progression of acute and chronic dermatitis can be further complicated by other superimposed factors, notably physical injury from self-trauma, secondary bacterial infection of traumatized surface, injury from insect bites attracted by odor or exudate, and moderation by the host immune response or therapy. Thus dermal inflammatory responses to different stimuli often have overlapping histologic features, providing a diagnostic challenge for the dermatopathologist. Even so, the distribution of leukocytes often evolves into recognizable patterns that, when combined with the inflammatory cell type, suggest a group of differential diagnoses or the cause or pathogenesis of a specific disease (Tables 17-3 and 17-4). Dermal patterns of inflammation that have been used in histologic diagnosis include perivascular dermatitis, interface dermatitis (mild inflammation affecting the basilar epidermis and superficial dermis that often obscures the epidermal dermal interface), nodular to diffuse dermatitis with infectious agents, and nodular to diffuse dermatitis without infectious agents (Fig. 17-24). For example, perivascular dermatitis with eosinophils is suggestive of hypersensitivity associated with parasites or other antigens; interface dermatitis with lymphocytes is suggestive of an immune response directed toward epidermal cells, such as lupus erythematosus or erythema multiforme; and nodular dermatitis with macrophages (granulomatous dermatitis) indicates a persistent stimulus, such as infection with acid-fast bacteria or fungi. Thus patterns of inflammation combined with cellular composition of infiltrates are useful in microscopic diagnosis.

1139

1140

**Fig. 17-24 Schematic diagram of the inflammatory patterns of the dermis.** **A**, Perivascular: Leukocytes (*black dots*) migrate from the dermal vessels into the perivascular dermis. This is the least specific pattern because all inflammatory patterns are at one stage perivascular. **B**, Vascular (vasculitis): Leukocytes target the vessel wall, resulting in necrosis, inflammation, leakage of fibrin and red blood cells, and if severe, thrombosis and infarction. **C**, Interface, cell poor: Mild, often lymphocytic, inflammation located along the epidermal dermal interface with vacuolar or apoptotic degeneration of basal cells. **D**, Interface, cell rich: Dense band of inflammation along the epidermal dermal interface, obscuring the basilar layer of the epidermis, and with vacuolar or apoptotic degeneration of basal cells. **E**, Nodular to diffuse with or without microorganisms: Inflammation, typically granulomatous to pyogranulomatous, which partially effaces the architecture of the dermis. May be associated with infectious agent or may be sterile. (*A through E, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics; and Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.1.4.3 RESPONSES OF THE ADNEXA TO INJURY

The term “adnexa” refers to appendages or adjunct parts, which in the skin includes hair follicles and glands. The major clinical and histologic changes involve the hair follicles, and thus follicular lesions will be emphasized in the following discussion.

1140

1141

#### 17.1.4.3.1 Alterations in Maintenance, Growth, and Development

##### 17.1.4.3.1.1 Atrophy

Atrophy refers to gradual reduction (involution) in size and can be physiologic or pathologic. Physiologic atrophy is related to the normal progression of the hair follicle cycle (i.e., the hair cycle stages of growth [anagen], transition [catagen], rest [telogen], and shed [exogen]). Pathologic atrophy occurs when the degree of atrophy is greater than that expected for a given stage of the hair cycle. Causes of follicular atrophy include hormonal abnormalities, nutritional abnormalities, inadequacy of blood supply, inflammation, and general state of health, including stressful events or systemic illness. Some types of pathologic atrophy can be reversed when the underlying cause is corrected. Damage to germinal epithelium can result in destruction or total loss of the adnexa with replacement by a scar. Examples include extensive inflammation and disruption of the follicle (folliculitis and furunculosis) and bordering glands and dermis that destroy a significant portion of the adnexal germinal epithelium, thermal burns sufficiently deep to involve the adnexa and dermal vessels, thrombosis causing infarction (i.e., diamond skin disease in pigs), and severe physical trauma, such as lacerations that remove components of the skin including adnexa.

##### 17.1.4.3.1.2 Hypertrophy

Hypertrophy is an increase in the unit size of a structure or an individual cell. Follicular hypertrophy, follicles that are longer and wider than normal for the site, develops secondary to repeated surface trauma, such as in acral lick dermatitis. Hyperplasia is an increase in the number of cells in a structure. Enlargement of adnexa, a common response to injury, usually involves both hypertrophy and hyperplasia, and is observed in follicles and sebaceous and apocrine glands associated with chronic allergic dermatitis.

##### 17.1.4.3.1.3 Abnormalities of hair cycle stages

Abnormalities of hair cycle stages occur when there is disruption in the normal progression from the anagen, catagen, telogen, and exogen stages of the hair cycle (Fig. 17-6). Clinical and histologic lesions are diverse. Some animals have failure of hair to regrow after clipping (hypothyroidism, post clipping alopecia). Other animals have sudden shedding of hair coat (synchronous change of many follicles from telogen into anagen, resulting in loss of old telogen hair shafts as new hair shafts emerge, termed “telogen effluvium”). Yet other animals have gradual, but progressive, loss of hair shafts associated with endocrine disease, such as hyperadrenocorticism.

### Follicular dysplasia

Follicular dysplasia refers to incomplete or abnormal development of follicles and hair shafts. Different types of follicular dysplasia syndromes are described, but most are poorly characterized. Microscopic features vary but include abnormal keratinocytes in the hair matrix or abnormally formed follicles, which produce abnormal hair shafts, resulting clinically in a reduced or absent hair coat. The lesions of follicular dysplasia that are most easily recognized microscopically are color associated and include color mutant alopecia (color dilution follicular dysplasia) and black hair follicular dysplasia (Fig. 17-25) in which melanin pigment abnormalities serve as a marker for the dysplasia. These pigment abnormalities include abnormally clumped melanin pigment granules in melanocytes in the epidermis and follicular hair matrix cells; and irregularly sized, shaped, and distributed melanin pigment clumps in hair shafts; and macrophages containing melanin pigment and located in the perifollicular dermis. The pathogenesis of the abnormal hair coat appears to involve breakage of hair shafts in areas of large pigment clumps, an abnormality of development of the cuticle, and also possibly an abnormality of hair shaft development caused by damaged hair matrix cells.

1141

1142

**Fig. 17-25 Black hair follicular dysplasia, skin, dog. A,** Large and variably sized and shaped melanin pigment granules are present in hair shafts and hair matrix cells (*arrows*). Macrophages that have phagocytosed melanin pigment are present in the dermis, most prominently near hair bulbs. The melanin presumably comes from damaged hair matrix cells. H&E stain. **B,** Note alopecia in black-haired area and normal hair coat in white-haired area. The skin in the black-haired area is pigmented; thus alopecia is not easily recognized from a distance. (**A,** Courtesy Dr. Ann M. Hargis, *DermatoDiagnostics*. **B,** Courtesy Blackwell Publishing.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.1.4.3.2 Adnexal Inflammatory Disorders

#### 17.1.4.3.2.1 Folliculitis

Folliculitis is inflammation of a hair follicle. Folliculitis can be histologically classified according to the anatomic segment of the hair follicle affected and the type of leukocytes present in the inflammatory infiltrate (Fig. 17-26). The types of follicular inflammation include perifolliculitis, mural folliculitis, luminal folliculitis, and inflammation of the hair bulb (bulbitis). The inflammation of hair follicles begins in the perifollicular blood vessels with the same hemodynamic, permeability, and leukocytic changes that comprise dermal inflammation. Leukocytes migrate from perifollicular blood vessels to the dermis, resulting in perifolliculitis (inflammation around, but not involving, the hair follicle). Perifolliculitis is not specific for any category of disease but is an initial event in the development of folliculitis. Perifolliculitis also often coincides with folliculitis of a variety of causes.

1142

1143

The perifollicular inflammatory cells then migrate into the follicular wall, resulting in mural folliculitis (inflammation limited to the wall of the follicle). Depending on the cause of the inflammatory process, the leukocytes can remain localized to the follicular wall or can progress into the follicular lumen.

Fig. 17-26 **Schematic diagram of the inflammatory patterns of the adnexa.** **A**, Perifollicular: Leukocytes (*black dots*) migrate from the dermal vessels near follicles into the perifollicular dermis. **B**, Mural folliculitis: Inflammation targets the follicular wall. There are subtypes of mural folliculitis that vary with level of involvement (superficial versus inferior), type of the inflammation (pustular versus necrotizing), and the degree or severity of penetration into the follicular wall (interface versus infiltrative). **C**, Luminal folliculitis: Inflammatory exudate is present in the follicular lumen, and inflammation also usually involves the wall, often a response to follicular infection. **D**, Furunculosis: Disruption of the follicular wall resulting in release of luminal contents into the bordering dermis. **E**, Bulbitis: Inflammation targeting the inferior segment of the hair follicle, also called the “hair bulb.” **F**, Sebaceous adenitis: inflammation targeting the sebaceous glands. (*A through F, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics; and Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.*)

17.1.4.3.2.1.1

### Mural.

In mural folliculitis, leukocytes remain largely confined to the follicular wall. Mural folliculitis is further subdivided by the location, type, or severity of involvement of the follicular wall, such as interface (outer aspect of the follicular wall), infiltrative (more infiltration into the follicular wall), pustular (presence of pustules in the follicular wall), or necrotizing (necrosis and disruption of the follicular wall). The subtype of mural folliculitis can provide insight into the pathogenesis of folliculitis (e.g., disease process). For example, pustular mural folliculitis is a feature of pemphigus foliaceus, and interface mural folliculitis is a feature of demodicosis ([Fig. 17-27](#)).

Fig. 17-27 **Demodicosis, skin, dog.** **A**, Note mites deep in the lumens of follicles (*arrow*) and also inflammation in the outer wall of the follicle (interface mural folliculitis) and in the perifollicular dermis (perifolliculitis). H&E stain. **B**, Note the mite in the follicular lumen. There are a few lymphocytes bordering the follicular wall and mild vacuolar degeneration of basal cells (*arrows*) (lymphocytic interface mural folliculitis) of the follicular wall. H&E stain. **C**, Localized demodicosis, periocular. Skin is alopecic, lichenified, and hyperpigmented. Alopecia is likely due to inflammation, initiated by an immune response to mite infestation and possibly secondary bacterial infection, that results in damage and sometimes disruption of the follicular wall (furunculosis). (**A**, **B**, and **C**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.1.4.3.2.1.2

## Bulbitis.

1144

Bulbitis refers to inflammation directed at the deepest portion of the follicle, the hair bulb. Alopecia areata is a specific example of bulbitis. It develops in horses, dogs, cats, and cattle; is characterized by lymphocytic infiltrates around and in growing hair bulbs; and results in alopecia. In dogs and horses, antifollicular cell-mediated immunity and humoral immunity participate. Cellular infiltrates of the hair bulb are mostly cytotoxic CD8<sup>+</sup> lymphocytes and CD1<sup>+</sup> dendritic antigen-presenting cells, whereas CD8<sup>+</sup> and CD4<sup>+</sup> lymphocytes predominate in the peribulbar infiltrate. Autoantibodies target trichohyalin, hair keratins, and other components of the hair follicle. The damage to hair matrix cells within the hair bulb results in formation of dystrophic (abnormal) hair shafts. Alopecia areata can spontaneously resolve, but the newly growing hairs can be white instead of pigmented, probably as a result of damage to melanocytes in the hair bulb.

17.1.4.3.2.1.3

## Luminal.

Luminal folliculitis refers to inflammation involving the lumen of the follicle and usually the wall of the follicle (Fig. 17-28). Luminal folliculitis develops when the leukocytes in the follicular wall migrate into the lumen, usually as a result of a stimulus in the follicular lumen, such as a follicular infection with bacteria (staphylococci) or dermatophytes (*Microsporum*, *Trichophyton*), or infestation with parasites (*Demodex*, *Pelodera*). The inflammation can weaken the follicular wall leading to rupture, known as furunculosis (Fig. 17-29), and release of follicular contents into the dermis. There are other causes of furunculosis, including trauma to the surface of the skin resulting in epidermal hyperplasia at the opening of the follicle, plugging of the follicle by stratum corneum, and accumulation of follicular contents including glandular secretions (comedo formation). The gradual accumulation of this luminal material can cause thinning of the follicular wall, leading to rupture. Regardless of the cause of furunculosis, the presence of hair fragments, keratin proteins, sebum, and possible infectious agents in the dermis leads to a suppurative inflammatory response that progresses to more long-standing chronic pyogranulomatous inflammation and scarring. Perifolliculitis, luminal folliculitis, and furunculosis often follow in sequence (Fig. 17-30). The inflammation can resolve with appropriate therapy, can extend into the deep dermis and panniculus, and/or can form sinuses that drain to the surface of the skin and are difficult to resolve. Severe inflammation can lead to complete destruction of adnexal units and replacement by scar tissue.

17.1.4.3.2.2

## Sebaceous adenitis

Sebaceous adenitis is a specific inflammatory reaction that targets sebaceous glands; it occurs in dogs (Fig. 17-31) and rarely in cats. Early lesions are characterized by accumulations of lymphocytes around sebaceous ducts. Fully developed lesions consist of lymphocytes, neutrophils, and macrophages that efface sebaceous glands. Chronic lesions have total loss of sebaceous glands (atrophy), scarring, and epidermal and follicular hyperkeratosis. Sebaceous gland inflammation also can occur secondary to folliculitis, demodicosis, uveodermatologic syndrome, or leishmaniasis, in which the inflammation targets other areas of the skin (follicles, epidermal cells, or dermis) and involves the neighboring sebaceous glands because of their proximity to the inflammation.

1144

1145

Fig. 17-28 **Folliculitis, skin, haired, dog.** **A**, Luminal folliculitis. Note the distention of hair follicle with inflammatory cells (mostly neutrophils). H&E stain. **B**, Multiple alopecic papules are caused by perifollicular inflammation and edema and hair follicles distended with exudate. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

**Fig. 17-29 Folliculitis and furunculosis, skin, haired, dog.** **A**, The wall of the follicle has become disrupted, resulting in the release of follicular contents (a hair shaft, stratum corneum of the follicle, and exudate) into the dermis. The follicular lumen also contains numerous coccoid bacteria (*arrow*). The hair shaft has variably sized and shaped melanin pigment granules, indicating that this dog also had coat color dilution. H&E stain. **B**, A circular area of erythema, scaling, and crusting is caused by follicular inflammation and rupture (furunculosis). The inflammation in the perifollicular dermis has extended into the surrounding dermis and formed a draining sinus to the epidermal surface. The exudate on the surface has dried to form a crust. (**A and B**, Courtesy Dr. Ann M. Hargis, *DermatoDiagnostics*.)

Fig. 17-30 **Schematic diagram of the progression of folliculitis.**

Inflammation begins with migration of leukocytes (*black dots*) from perifollicular dermal vessels into the perifollicular dermis (perifolliculitis). Inflammation progresses to involve the follicular wall (mural folliculitis) and then the lumen (luminal folliculitis). If the inflammation continues, the follicular wall is weakened, ruptures, and follicular contents are released into the dermis. The inflammation can extend into the deep dermis and panniculus, and/or form sinuses that drain to the surface of the skin. (*Redrawn with permission from Dr. Ann M. Hargis, DermatoDiagnostics; and Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.*)

### 17.1.4.3.2.3

#### Hidradenitis

Hidradenitis, inflammation of apocrine glands, has rarely been studied in detail in domestic animals. Suppurative hidradenitis has been described in dogs in which most cases developed in conjunction with staphylococcal folliculitis and furunculosis, either affecting the same or other follicular units. It is speculated, because of the physical connection between the apocrine gland and hair follicle in dogs, that suppurative hidradenitis is most often an extension of hair follicle infection and is due to the bacteria that cause the folliculitis (usually *Staphylococcus intermedius*). There are no clinical signs that are unique to or suggest the presence of hidradenitis other than the association with follicular bacterial infection. Histologically, dogs with hidradenitis associated with bacterial folliculitis and furunculosis have suppurative inflammation of the apocrine gland and surrounding dermis.

1145

1146

Fig. 17-31 **Sebaceous adenitis, skin, haired, dog.** **A**, Note the inflammation (*I*) concentrated in and around sebaceous glands. The inflammation forms a band of inflammatory cells parallel to the epidermis at the level of the sebaceous glands. H&E stain. **B**, Inflammation is beginning to efface the sebaceous glands. A few sebaceous glands (*arrows*) are visible within the area of inflammation. H&E stain. **C**, Alopecia and scaling are evident. The pathogenesis of the alopecia and scaling is incompletely understood. (**A**, **B**, and **C**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

---

### 17.1.4.4 RESPONSES OF THE VESSELS TO INJURY

Vasculitis, inflammation of vessels (Fig. 17-24) in which the vessels are the primary target of injury, can be the result of infection by microbes, immunologic injury, toxins, or disseminated intravascular coagulation or can be idiopathic. The species most commonly presenting with vasculitis are the horse and the dog, and most cases are idiopathic in that a specific cause cannot be determined. Histologic diagnosis of vasculitis is often challenging because it is often difficult to differentiate between vessels taking part in inflammation simply by providing a conduit for inflammatory cells to reach a site of injury in the epidermis or dermis from those vessels that are actually the target of injury. Also, the type of inflammatory cell that participates in the inflammatory process can vary more with the age of the vascular lesion than with the type of disease process. Histologic lesions in vasculitis include damage to the vessel wall, such as the presence of few necrotic cells or foci of fibrinoid necrosis, mural infiltrates of leukocytes, and intramural or perivascular edema, hemorrhage, or fibrin exudation. Vascular injury leads to the clinical lesions of edema and hemorrhage and, if severe, can include ischemic necrosis and infarction. Ulceration with or without sloughing of the skin can occur. Classic examples include immune-complex deposition in vessel walls (systemic lupus erythematosus), infection with an endotheliotropic organism (*Rickettsia rickettsii*), and septicemia with bacterial embolism and infarction in pigs (*Erysipelothrix rhusiopathiae*).

### 17.1.4.5 RESPONSES OF THE PANNICULUS TO INJURY

#### 17.1.4.5.1 Panniculitis

Panniculitis, inflammation of the subcutaneous adipose tissue, can be caused by infectious agents (bacteria, fungi), immune-mediated disorders (systemic lupus erythematosus), physical injury (trauma, injection of irritant material, foreign bodies), nutritional disorders (vitamin E deficiency), or pancreatic disease (pancreatitis, pancreatic carcinoma) or can be of undetermined cause (idiopathic). Panniculitis can be primary or secondary. In primary panniculitis, the subcutaneous adipose tissue is the target of the disease process (Fig. 17-32). An example of primary panniculitis is feline pansteatitis, which occurs in cats fed diets high in polyunsaturated fats and low in antioxidants, such as vitamin E. Lack of vitamin E leads to oxidation of lipids (free radical-induced membrane lipid peroxidation) of the subcutaneous adipose tissue, inciting a pyogranulomatous inflammatory response. In secondary panniculitis, the subcutis is affected by inflammation primarily involving the contiguous dermis; the inflammation extends down into the subcutis. For example, deep bacterial folliculitis with furunculosis can lead to a secondary panniculitis, as can a penetrating wound contaminated with microbial agents or a foreign body. Animals with panniculitis clinically have palpable nodules that can ulcerate and drain an oily or hemorrhagic material. Lesions are most often on the trunk and proximal limbs and can be solitary or multifocal. Solitary lesions may be cured by excision, whereas multiple lesions may resolve with specific therapy or result in scar formation. In animals, panniculitis is subdivided based on cell type and presence or absence of microorganisms into the following basic categories: predominantly neutrophilic, predominantly lymphocytic, predominantly granulomatous to pyogranulomatous with infectious agents, and predominantly granulomatous to pyogranulomatous without infectious agents.

1146

1147

**Fig. 17-32 Schematic diagram of inflammation in the panniculus.** Note the leukocytic inflammation (*black dots*) in the subcutaneous adipose tissue (panniculitis). In addition to spreading locally, the inflammation can form a sinus through the dermis and epidermis to the surface. The exudate can have an oily composition due to the fat content of the panniculus. (*Redrawn with permission from Dr. Ann M. Hargis, DermatoDiagnostics; and Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.*)

17.1.4.6

### PATHOLOGIC REACTIONS OF THE ENTIRE CUTANEOUS UNIT

Disease processes involving the skin uncommonly affect just one component of the skin (i.e., only the epidermis or only the lumens of hair follicles). More often, multiple components of the skin are involved in the disease process. In addition, lesions evolve through different stages; some lesions can resolve, and there can be secondary lesions, such as self-induced trauma, complicating the initial lesions. Therefore multiple biopsy samples collected from different areas of the skin are often necessary to help illustrate the range of lesions necessary to reach a diagnosis. Multiple biopsy samples provide a more representative picture of the disease process than could a single biopsy sample. Even so, evaluation of multiple biopsy samples does not always lead to a specific diagnosis, but the pattern of lesions identified often suggests categories of disease and rules out other differential diagnoses.

The involvement of the multiple components of the skin in a disease process can be illustrated by a poxvirus infection ([Fig. 17-33](#)). When a poxvirus invades the epidermis, the virus replicates in the cells of the stratum spinosum and causes cytoplasmic swelling (ballooning degeneration) and rupture (reticular degeneration) of some of the epidermal cells. Cytoplasmic viral inclusions form in some cells. Cellular

## Pathologic Basis of Veterinary Disease, 4th Edition

---

constituents released from damaged epidermal cells act as chemical mediators of the acute inflammatory response and are chemotactic for leukocytes. These chemical mediators and chemotactic factors: (1) increase blood flow to the site of viral invasion by dilation of arterioles, (2) cause margination of leukocytes in capillaries and postcapillary venules in the dermis, (3) increase vascular permeability (dermal edema), and (4) cause migration of leukocytes out of vessels into the tissue, creating the formation of macular lesions. The epidermal degeneration, dermal edema, and perivascular inflammation can progress to exudative lesions. Ballooning and reticular degeneration of keratinocytes result in the formation of intraepidermal vesicles. Leukocytes in perivascular sites under the influence of inflammatory mediators from the epidermis migrate to the epidermis and enter the vesicle to form pustules. Some poxviruses also cause epidermal hyperplasia by stimulating host cell DNA synthesis, presumably by a viral gene product similar to epidermal growth factor, resulting in pseudoepitheliomatous hyperplasia. The pustule enlarges and eventually ruptures, releasing the exudates onto the skin surface. The exudates dry and form a crust (scab). The primary lesions of vesicles and pustules are fragile and often transient, lasting only hours, and so are difficult to identify and collect in biopsy samples. The secondary lesions of crusting and scarring are more long-standing. In this way, multiple components of the skin participate in the development of the lesions and are responsible for the clinical stages of macule, papule, vesicle, pustule, crust, and scar.

1147

**Fig. 17-33 Schematic diagram of the development of a poxvirus lesion over time.** **A**, Ballooning degeneration. **B**, Reticular degeneration with cytoplasmic inclusion bodies of keratinocytes are subclinical stages. **C**, Congestion, edema, margination, and migration of leukocytes (*black dots*) form the macule stage. **D**, Continued epidermal reticular degeneration, epidermal hyperplasia (acanthosis), dermal edema, and perivascular inflammation form the papule stage. **E**, The vesicle stage develops by coalescing of areas of reticular degeneration (disruption of swollen keratinocytes). **F**, Inflammatory cells migrate from the dermal vessels into the vesicle and accumulate in the vesicle to form the pustule stage. **G**, The epidermis begins to proliferate and becomes more acanthotic, and the old pustule is moved toward the epidermal surface. **H**, Epidermal hyperplasia progresses with the formation of elongated epidermal dermal interdigitations, and the old pustule ruptures to form a crust. Larger pustules can be umbilicated, involve the dermis, and result in scarring. (*A through H, Courtesy Dr. Ann M. Hargis, Dermato Diagnostics; and Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.*)

#### 17.1.5 DEFINITIONS OF CLINICAL TERMS

Knowledge of the clinical appearance of skin lesions, distribution of lesions, and correlation between the gross and histologic lesions is often critical in formulating differential and final diagnoses. In skin diseases, the clinical lesions represent the gross lesions and are typically examined by a practitioner, not the pathologist; thus the practitioner essentially serves as the eyes for the pathologist. It is therefore important for the practitioner to develop the ability to accurately recognize clinical lesion morphology and translate that information to the pathologist. To facilitate this process, [Table 17-5](#) is provided to illustrate the morphology of the various clinical lesions and provide examples of the disease processes in which those lesions occur.

### 17.1.6 TECHNIQUES FOR SKIN BIOPSY SAMPLING

Important tips for biopsy sampling of the skin are listed in [Table 17-6](#). Biopsy do's and don'ts are listed in [Boxes 17-5](#) and [17-6](#), respectively.

#### 17.1.6.1 WHEN TO COLLECT BIOPSY SAMPLES

Knowing when to collect biopsy samples helps obtain the most diagnostic samples; facilitates obtaining samples early so acute, serious, or neoplastic disorders are diagnosed quickly; and prevents the frustration and economic loss when samples are inappropriately collected, such as when concurrent therapy might alter diagnostic lesions, when lesions are in a quiescent stage and might not be diagnostic, and when dermatologic evaluation would have been a better method of achieving a diagnosis. Biopsy sampling is recommended when:

1. The therapy for the skin disorder is associated with significant side effects (to confirm the clinical diagnosis before starting therapy).

1148

2. A nodular lesion, ulcer, or nonhealing wound might represent a tumor (so that surgical excision of the tumor can be performed as early as possible).

1154

3. Lesions develop suddenly, are severe, or are unusual (to help identify a serious disease so that therapy can be instituted early).

4. Lesions develop during the course of therapy (to identify a potential adverse reaction to drug therapy).

5. When lesions are active and before use of therapy that might alter the histologic appearance of the lesions, and when there are multiple clinical differential diagnoses and the thorough dermatologic and clinical examinations do not differentiate the conditions (so samples are collected in their early stage, and when other means of diagnosis are insufficient).

6. When a skin disorder fails to respond to apparently appropriate therapy or when the disorder responds to therapy but recurs when therapy is stopped (to establish the correct diagnosis, or evaluate for predisposing factors). Recall that antiinflammatory therapy can alter lesions.

##### 17.1.6.1.1 Box 17-5 Biopsy Sampling Do's

Be gentle

Biopsy early

Collect multiple samples representative of the range of lesions

Include crusts

Biopsy before using antiinflammatory therapy

Use the correct biopsy procedure for the type of lesion

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Label samples from different areas

Prevent samples from freezing

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-5 Definition and Morphology of Primary and Secondary Skin Lesions

Lesion Definition	Drawing	Clinical Photograph
<b>NORMAL SKIN</b> <b>Callus</b> Thick, hard, hairless plaque with increased skin creases Example: Trauma over bony prominence such as elbow or sternum		
<b>Comedo</b> Plug of stratum corneum and sebum ( <i>arrows</i> ) within the lumen of a hair follicle Examples: Canine actinic dermatosis, chin acne, Schnauzer comedo syndrome, hyperadrenocorticism		
<b>Crust</b> Dried exudate on the skin surface Example: Chronic stage of pustular disease such as staphylococcal infection or pemphigus foliaceus		
<b>Cyst</b> Cavity lined by epithelium and filled with liquid or semisolid material and located in the dermis or subcutis Examples: Follicular cyst, dermoid cyst		
<b>Epidermal Collarette</b> Flat to minimally elevated ring ( <i>arrows</i> ) of scale that enlarges peripherally Examples: Superficial bacterial infection, insect bite, fungal infection		
<b>Erosion</b> Loss of part of the epidermis; depressed, moist, glistening ( <i>arrows</i> ) Examples: Secondary to vesicle or pustule rupture or secondary to surface trauma		
<b>Excoriation</b> Linear loss of epidermis ( <i>arrows</i> ) Example: Abrasion or scratch		
<b>Fissure</b> Linear crack or break ( <i>arrows</i> ) from the epidermis to the dermis Examples: Footpad fissure seen in pemphigus foliaceus, superficial necrolytic dermatitis, or digital hyperkeratosis		
<b>Lichenification</b> Rough, thickened epidermis secondary to persistent rubbing, scratching, or irritation Example: Chronic dermatitis		
<b>Macule</b> Flat, circumscribed area that is a change in the color of the skin, <1 cm in diameter Examples: Hemorrhage, lentigo, vitiligo		

## Pathologic Basis of Veterinary Disease, 4th Edition

### Neoplasm<sup>\*</sup>

"An abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of normal tissue and persists in the same excessive manner after cessation of the stimuli, which evoked the change"<sup>†</sup>

Examples: Lipoma, mast cell tumor, squamous cell carcinoma

### Nodule<sup>‡</sup>

Elevated, firm, circumscribed lesion 1–2 cm in diameter

Examples: Bacterial or fungal infection, infectious or sterile granuloma

### Papule

Elevated, firm, circumscribed area <1 cm in diameter (*arrows*)

Examples: Insect bite, papilloma, superficial folliculitis

### Plaque

Elevated, firm, lesion with a flat top surface >1 cm in diameter

Examples: Calcinosis cutis, reactive histiocytosis, eosinophilic plaque

### Pustule, Epidermal<sup>\*</sup>

Elevated superficial accumulation of purulent fluid within the epidermis (*arrow*)

Examples: Bacterial infection, pemphigus foliaceus

### Scale

Fragmented, keratinized cells, flaky skin, irregular, thick or thin, dry or oily

Examples: Cornification disorders, sebaceous adenitis, ichthyosis

### Scar

Thin to thick fibrous tissue that replaces normal skin following injury or laceration to the dermis

Examples: Healed wound, surgical scar

### Ulcer<sup>\*</sup>

Loss of epidermis and basement membrane with exposure of dermis, concave

Examples: Ischemic lesions resulting from vasculitis, indolent ulcer, feline herpesvirus infection, feline ulcerative dermatosis syndrome

### Vesicle and Bulla<sup>†</sup>

Vesicle: Elevated, circumscribed, fluid-filled lesion <1 cm in diameter

Bulla: A large vesicular lesion >1 cm in diameter (*arrows*)

Examples: Burn, viral infection, immunemediated diseases such as bullous pemphigoid

## Pathologic Basis of Veterinary Disease, 4th Edition

### Wheal\*

Elevated, irregular-shaped area of cutaneous edema; solid, transient (*arrows*)

Examples: Insect bites, urticaria, allergic reaction

1154

### Table 17-6 Biopsy Sampling Tips

1155

Preparation	Very gently clip or scissor if necessary Do not surgically prepare the site if sampling lesions in epidermis or dermis Caveat: Can surgically prepare site for excision of lesions deep in the subcutis or to remove large nodular mass, such as a neoplasm
Lesions	Collect <i>multiple</i> samples representative of the range of lesions If crusting is significant, collect crust, wrap in lens paper, and place in formalin For <i>alopecic</i> conditions: Collect samples from the most alopecic areas; draw a line on the sample in the direction of the hair coat For <i>ulcers or depigmenting lesions</i> (junction important): Use incisional or excisional method or use an 8-mm biopsy punch instrument, and draw a line on the sample perpendicular to the junction between lesion and normal skin
Punch samples	Use 6- or 8-mm punch instruments for haired skin Use 4-mm punch for periocular skin, footpads, or nasal planum
Incisional and excisional samples	Use incisional or excisional methods if smaller punch would damage large pustule or vesicle Gently place thin incisional or excisional samples, subcutis side down, on a piece of cardboard; let adhere for about 30 seconds, then place in formalin (prevents warping); Note: Do not let sample dehydrate For lesions in the panniculus, use incisional or excisional method to ensure that the sample is of sufficient size and depth for diagnosis
Fixation	Fix samples in 10% buffered formalin with 10 times the volume of formalin for the volume of samples For diagnosis of autoimmune skin disease or tumors, begin with standard histopathology; selected immunohistochemical stains can usually be done later on the formalin-fixed samples if desired
Important finale	Submit a history with differential diagnoses

17.1.6.1.2

### Box 17-6 Biopsy Sampling Don'ts

Do not surgically prepare the site if lesions are in the epidermis or dermis

Do not use electrocautery or laser for small biopsy samples

## Pathologic Basis of Veterinary Disease, 4th Edition

Do not grasp the punch biopsy samples or lesion areas of larger samples with a tissue forceps

Do not use a biopsy instrument that is too small (4 mm is the *minimum* useful diameter)

Do not forget to collect multiple samples

Do not forget to submit a history

17.1.6.2

### SITE SELECTION

Multiple cutaneous sites representative of the range of lesions should be selected for biopsy. Fully developed nontreated primary lesions, such as macules, papules, pustules, nodules, neoplasms, vesicles, and wheals, are often the most useful for diagnosis (Table 17-5). However, primary lesions may not be present at the time the animal is examined, so secondary lesions, such as scales, crusts, ulcers, comedones, or scars then need to be sampled and evaluated (Table 17-5). These secondary lesions can be diagnostic or contribute substantially to the diagnosis when multiple cutaneous sites are selected for biopsy. One of the most useful secondary lesions is the crust, because acantholytic cells from drying pustules in pemphigus foliaceus and organisms, such as *Dermatophilus congolensis* or dermatophytes, may be identified in crusts, providing the information necessary for diagnosis. Also, the margin of a chronic ulcer may represent a squamous cell carcinoma, or the scale at the edge of an epidermal collarette (i.e., peripherally expanding ring of epidermal scales) may represent superficial spreading pyoderma, thus providing the key to diagnosis.

1155

17.1.6.3

### METHODS

Excisional biopsy samples (entire lesions) are recommended for large pustules or vesicles that can be damaged by use of a smaller punch biopsy instrument. Deeper excisional biopsy samples are generally necessary for diagnosis of lesions, such as panniculitis, that are deep to the epidermis and dermis. Digital amputation can be required, particularly in dogs, for the diagnosis of claw bed lesions. Electrocautery or laser should not be used for small biopsy samples because the samples can be damaged and rendered nondiagnostic. Tissue forceps should grasp, if at all, only one nonaffected margin, preferably in the subcutis.

1156

17.1.6.4

### SITE PREPARATION

Generally the skin at a punch biopsy site should not be surgically prepared because the procedure may remove a diagnostic portion of the sample (Fig. 17-16). Gentle clipping of hair is acceptable, but for an excisional biopsy of lesions deep to the epidermis, surgical preparation of the skin is acceptable. For collection of biopsy samples in areas of alopecia, drawing a line with a fine-tipped permanent marking pen in the direction of the hair coat helps laboratory personnel orient the sample (Fig. 17-34, A). In the laboratory, the sample is cut along the line so that the hair follicles are oriented longitudinally (Fig. 17-34, B). If the line is not drawn on the sample, the sample might be cut so that the follicles are in cross or tangential section rather than longitudinal section (Fig. 17-34, C), which reduces histologic value of the sample when evaluating for follicular disease. For collection of ulcers, depigmented lesions, or other lesions where the interface between normal and affected skin is critical to diagnosis, use of incisional or excisional samples collected from affected skin and contiguous normal skin is often preferable. However, a large (8 mm) biopsy punch instrument can be used to collect the junction between normal and affected skin if a line with a fine-tipped permanent marking pen is drawn perpendicular to the junction between the normal and affected tissue before sample collection (Fig. 17-35). The line instructs laboratory personnel

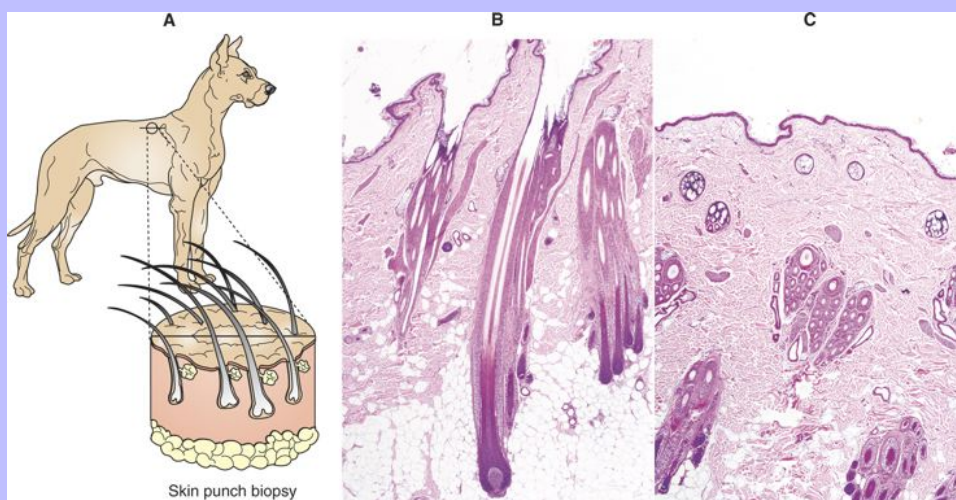

1156

1157

## Pathologic Basis of Veterinary Disease, 4th Edition

how to trim the sample to ensure that the critical areas are present for dermatopathologic evaluation. For lesions suspected of being invasive tumors, complete excision of the mass, including a 3-cm margin of clinically normal skin around all borders, is recommended (Fig. 17-36).

**Fig. 17-34 Sampling of the skin for histopathologic evaluation, haired, dog.** **A**, Schematic diagram of the line drawn (with fine tipped permanent marking pen) on the skin in the direction of the hair coat. The line directs laboratory personnel to cut and embed the sample parallel to the hair follicles. Cutting the sample parallel to the hair follicles allows visualization of the entire length of the follicles during microscopic examination, which facilitates evaluation for causes of alopecia. For simplicity, simple follicles are used in this illustration. **B**, Section of skin trimmed parallel to the hair follicles. Note that the hair follicles are cut longitudinally, and that the full length of the hair follicle is present. H&E stain. **C**, Section of skin trimmed in cross section to the hair follicles. Note that the hair follicles are cut tangentially, and that only portions of each follicle are present for examination, which reduces the ability to evaluate follicular morphology. H&E stain. (**B and C**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

**Fig. 17-35 Schematic diagram of collecting the margin of a lesion and normal skin using a large punch biopsy instrument (8 mm).** It is necessary to draw a line on the sample from normal into affected skin to direct laboratory personnel to cut and embed the sample so that the interface between the normal and affected skin is present for microscopic examination. Without this line, the sample could be cut at a right angle to the desired line and thus miss the interface between normal and affected skin essential for histologic examination of the area most likely to have diagnostic changes.

**Fig. 17-36 Schematic diagram of excisional sampling.** If possible, 3-cm margins should be collected if the nodule is suspected of being an invasive neoplasm. This facilitates examination of the margins for completeness of excision.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.1.6.5 **FIXATION**

Punch biopsy specimens should be placed in 10 times the volume of 10% neutral buffered formalin (NBF). To prevent warping in the fixative, thin excisional biopsy specimens should be gently attached to a flat object, such as a piece of cardboard or tongue depressor, and permitted to dry for 20 to 30 seconds. Twenty to 30 seconds is all that is necessary for the sample to adhere to the flat object. The specimen and flat object are then immediately immersed in formalin. Care should be taken not to let the sample become dehydrated (i.e., remain unfixed for longer than 20 to 30 seconds), which could damage the morphology of small samples and the lesions. In cold climates during winter months, adding 1 part alcohol to 9 parts 10% NBF reduces the chance of freezing of specimens during transport.

### 17.1.6.6 **HISTORY**

Accurate histopathologic diagnosis and interpretation require knowledge of the gross features of the lesions. Therefore it is essential to include with biopsy samples the following information: (1) age, breed, and sex of the animal; (2) location, gross appearance, and duration of the lesions; (3) presence or absence of lesion symmetry; and (4) presence or absence of pruritus affecting the animal ([Box 17-7](#)). Clinical information including results of laboratory evaluations (i.e., hemograms, serum biochemical analyses), results of skin cultures or scrapings, current medications, and response to therapy should be included along with a list of clinical differential diagnoses. History can be critical to reaching a diagnosis. For instance, presence of luminal and mural folliculitis with no apparent follicular infectious agents in H&E stained sections in conjunction with the history of lack of response to appropriate antibiotic therapy would suggest to the pathologist that a fungal stain to evaluate for occult dermatophyte infection should be performed. Without the history of lack of response to appropriate antibiotic therapy, the folliculitis could easily be presumed to be of bacterial origin, and a fungal infection missed.

#### 17.1.6.6.1 **Box 17-7 What Constitutes a History?**

Age, breed, sex

Lesion distribution

Lesion appearance and severity

Lesion duration

Influence of specific therapy and/or recent therapy that could change lesions

Other clinical problems

Laboratory analyte abnormalities

Differential diagnoses (important)

1157

### 17.1.6.7 ANCILLARY PROCEDURES

Other diagnostic procedures can supplement information gained from histologic examination of biopsy samples. These procedures include aspiration of pustule contents for cytologic evaluation, performing touch imprints of the cut surface of suspected neoplastic or infectious lesions for cytologic evaluation, aseptically collecting a tissue sample for microbiologic culture, and collecting biopsy samples of suspected immune-mediated diseases or poorly differentiated tumors for immunostaining. Use of immunostaining for identification of cell surface or cytoplasmic proteins (to aid in diagnosis of tumors) or for identification of immunoglobulin, complement, or other antigens (to aid in the diagnosis of immune-mediated skin disease, such as pemphigus) can be helpful in some cases.

Unfortunately, immunostaining techniques can give false-positive or false-negative results; thus they must be done in conjunction with standard histopathology. For autoimmune diseases, if immunofluorescence evaluation is desired, specimens can be fixed in Michel's medium, which preserves immunoglobulin and complement. If immunohistochemistry (immunoperoxidase) staining is desired, formalin-fixed samples are used; however, for best results, samples should not remain in formalin longer than 48 hours. Prolonged fixation in formalin results in cross-linking of proteins and false-negative results. For autoimmune disease, newer techniques that detect more specific antigens, such as desmoglein (transmembrane glycoproteins found in desmosomes that provide physical connections between keratinocytes), use of "salt-split" skin sections (a technique used in immunostaining of the skin where sodium chloride splits the epidermis from the dermis through the lamina lucida, allowing better differentiation of subepidermal bullous diseases), use of better substrates for indirect immunostaining, and use of immunoblotting and enzyme-linked immunosorbent assay (ELISA) techniques will improve diagnostic accuracy of immune-mediated skin diseases in the future. For identification of cell surface or cytoplasmic proteins in poorly differentiated tumors, evaluation of a series (panel) of antibodies is preferred because the pattern of staining with a panel of antibodies is more reliable than staining with one or two antibodies. Formalin-fixed specimens are acceptable for some procedures, but for others, fresh or frozen specimens are better. Discussion with a pathologist is recommended regarding when to use immunostaining procedures.

### 17.2 DISEASES OF THE SKIN

#### 17.2.1 CONGENITAL AND HEREDITARY DISORDERS

The terms "congenital" and "hereditary" are not synonymous. Congenital lesions develop in the fetus (in utero), are present at birth, and have a variety of causes. An example is hypotrichosis in the fetus associated with maternal dietary iodine deficiency. Inherited conditions are transmitted genetically and are not always manifested phenotypically in utero or at birth but may develop later in life. An example is sebaceous adenitis, which may not develop until 1 to 2 years of age or later.

##### 17.2.1.1 CONGENITAL ALOPECIA AND HYPOTRICHOSIS

Congenital alopecia or atrichia (absence of hair from skin where hair is usually present) and hypotrichosis (less than the normal amount of hair) have been reported in most species of domestic animals. In most instances, congenital hypotrichosis is a hereditary condition due to spontaneous genetic mutations affecting genes responsible for or influencing the normal development and/or maintenance of hair follicles or other components of the skin. In most cases, the exact mutation has not been identified. In some of these animals,

## Pathologic Basis of Veterinary Disease, 4th Edition

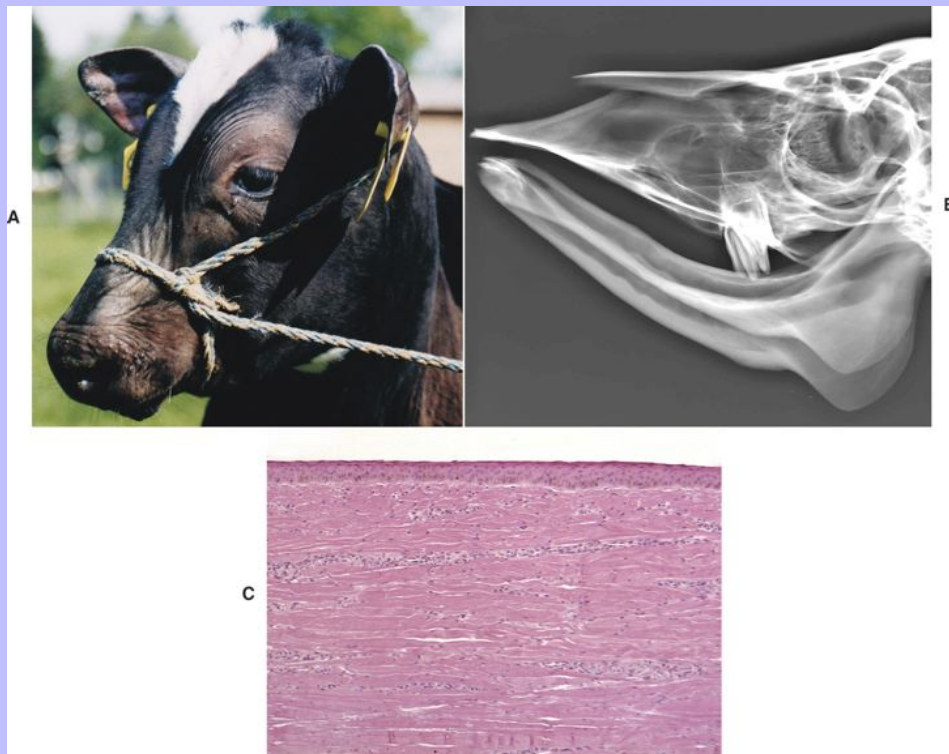

---

the alopecia or hypotrichosis has been recognized as standard for the breed (e.g., Mexican hairless dog, Sphinx cat, and Ulster pig), and the mutation is purposefully propagated. Animals with congenital hereditary hypotrichosis can have defects in other body systems, including brachygnathism (abnormal smallness of the mandible), and dental, thymic, and genital abnormalities. When the condition involves the hair follicles plus adnexal glands and teeth, which all arise from the ectoderm, the condition is also termed “ectodermal dysplasia.” In addition to health problems created by oral, dental, or thymic defects (inability to efficiently chew or graze and immune deficiency that can lead to death), animals with hypotrichosis are more susceptible to sunburn, temperature extremes, and bacterial and fungal infections. The degree, location, and age of onset of hairlessness vary. Hair that is present is usually abnormally coarse or fine and easily broken or epilated. Morphologic changes in the skin and hair follicles vary from species to species, most likely representing differences in mutations. A useful example is congenital hypotrichosis with anodontia in German Holstein calves ([Fig. 17-37](#)). In this condition, hypotrichosis, lack of most teeth, and complete absence of eccrine nasolabial glands is inherited as a monogenic X-linked recessive trait. Because the condition affects the hair follicles, some adnexal glands, and teeth, it is also classified as an ectodermal dysplasia. The condition varies in severity, with some calves more affected than others. Affected calves have reduced numbers of hairs per surface area in various anatomic locations (especially head, pinnae, neck, back, and tail), and also have reduced length and numbers of eyelashes and vibrissae. The alopecia and hypotrichosis are most severe in newborn calves because the presence of fine hairs increases with age. There are no defects in the horns, endocrine glands, genital organs, or other internal organs. Histologically, hair follicles and adnexal glands are absent in the skin on the back of the ears. Hair follicle density is often reduced in other areas. When present, hair bulbs are small and poorly developed. In some areas, the apocrine glands are reduced in quantity, and eccrine nasolabial glands are absent.

1158

1159

**Fig. 17-37 Congenital hypotrichosis with anodontia, calf.** **A**, The hair coat is sparse and short. Eyelashes and tactile hairs are also sparse and very short. The tail switch (not in this photograph) was about one third the normal length. **B**, Radiograph, skull. Note that most of the teeth are missing. When congenital hypotrichosis involves the hair follicles plus adnexal glands and teeth, which all arise from the ectoderm, the condition is also termed “ectodermal dysplasia.” **C**, Affected skin. Note the lack of hair follicles. Animals with hypotrichosis are susceptible to extremes of temperature, and the skin is more likely to sustain traumatic injury and secondary infection because of the lack of the protective hair coat. H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Especially for purposes of herd health management and disease prevention, it is important to differentiate the congenital inherited alopecia and hypotrichosis disorders from the nongenetic congenital alopecic disorders. The latter includes congenital hypotrichosis due to maternal iodine deficiency in pigs, calves, lambs, and foals; in utero infection with bovine virus diarrhea or hog cholera virus; and defects in other systems, such as adenohypophyseal hypoplasia in some breeds of cattle ([Table 17-7](#)).

It should be realized that there is some overlap between the congenital alopecia and hypotrichosis disorders and the follicular dysplasia disorders. Recall that follicular dysplasia is usually an inherited abnormality of

the hair follicles in which there is failure of hair growth, production of defective hair shafts, or failure to maintain hair within follicles ([Fig. 17-25](#)). The principal differentiating features include: (1) animals with follicular dysplasia having hair follicles that are defective or dysplastic, not absent or only reduced in number; (2) animals with follicular dysplasia having alopecia and hypotrichosis, which are not typically congenital, but develop in the months to years after birth; and (3) animals with follicular dysplasia typically not having defects in other organ systems. However, these differentiating features are not absolute. Consider, for example, that animals with congenital hereditary hypotrichosis and alopecia can have areas of the skin with hair, but the hair is abnormally coarse or fine and easily broken or epilated; thus they also technically have follicular dysplasia in some areas of the body.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-7 Categories, Causes, and Age of Onset of Hypotrichosis and Alopecia

Category	Cause	Age of Onset	Species
Congenital hypotrichosis or alopecia	Usually inherited, may be accompanied by odontogenic, thymic, genital, or other defects that influence neonatal viability	Usually present at birth or within the first month of life	Mostly calves; less often piglets, puppies, kittens; rarely foals
	Maternal dietary influences (e.g., iodine deficiency)	Present at birth	Calves, piglets, lambs, foals
	Secondary to other defects (adenohypophyseal hypoplasia)	Present at birth	Guernsey and Jersey calves
	In utero infection with bovine virus diarrhea or hog cholera virus	Present at birth	Calves, pigs
Follicular dysplasia	Usually inherited	Months to years after birth	Dogs, cattle, horses
Endocrine disorders and alopecia X in dogs*	Abnormal function of pituitary, thyroid, adrenal or pineal glands, or gonads; or iatrogenic administration of hormones	Develops in young adults to aged	Predominantly dogs
Hair cycle abnormalities	Nonendocrine factors that influence hair growth such as therapy with antimetabolic drugs (anagen defluxion), stress, fever, illness (telogen effluvium), or clipping plush-coated breeds of dogs (post clipping alopecia)	Typically adults	Any species, often dogs
Neoplasia	Paraneoplastic: internal malignancy, often of pancreas or liver	Aged	Cats
	Direct involvement of epidermis, dermis, or adnexa (example: epitheliotropic lymphoma)	Usually adult to aged	Dogs, cats
Inflammatory conditions	Follicular infection	Any age	Any species; dogs most frequently affected with follicular infection and sebaceous adenitis
	Posttraumatic and inflammatory		
	Sebaceous adenitis		
Excessive grooming	Hypersensitivity reactions or psychogenic causes	Any age	Most often affects cats
Nutrition	Severe protein or protein-calorie nutrition	Any age, especially young or pregnant	Any species

## Pathologic Basis of Veterinary Disease, 4th Edition

1. Alopecia X of Nordic breeds of dogs is a group of poorly characterized dermatoses, including castration responsive dermatosis, growth hormone responsive dermatosis, and follicular dysplasia in Siberian huskies or Alaskan malamutes.
2. Clinically manifested endocrine disease in cats is usually caused by hyperadrenocorticism where marked dermal atrophy leads to tearing of the skin with normal handling procedures. Alopecia can be a feature, but skin fragility is a more significant problem.
3. Clinically manifested endocrine disease in horses is usually caused by hyperadrenocorticism and is typified paradoxically by hypertrichosis rather than alopecia (possibly because of production of adrenal androgens, other hormones, or pressure of the pituitary on thermoregulatory areas of the hypothalamus).

\* Endocrine:

### 17.2.1.2 COLLAGEN DYSPLASIA AND MUCINOSIS

Collagen dysplasia (hyperelastosis cutis, dermatosparaxis, cutaneous asthenia) occurs in most domestic animals and comprises a clinically, genetically, and biochemically heterogeneous group of diseases that are rare. In each, skin tears easily, is hyperextensible, and loose, but the severity of these lesions varies among species. Specific enzyme defects of collagen synthesis or processing are the cause of some collagen dysplasia syndromes. Abnormal synthesis or processing of collagen leads to structurally abnormal dermal collagen that has decreased tensile strength. The causes of other collagen dysplasia syndromes have not been established. Gross lesions consist of cutaneous hyperextensibility and laxity (Fig. 17-38), frequent skin wounds that result even from normal handling and activity, and numerous scars, which are the result of previous tearing of the dermal connective tissues. Microscopic features vary among the different types of collagen dysplasia syndromes, and in some the skin is histologically normal. If microscopic lesions are present, the collagen bundles can vary in size and shape, can be separated by wide spaces, or have a haphazard arrangement. Electron microscopy or biochemical analyses are sometimes required to make a definitive diagnosis.

1160

1161

Mucinosis (mucin deposition in the dermis) occurs normally in some breeds of dogs, such as the Shar-Pei or in association with myxedema of hypothyroidism. The presence of mucin in the Shar-Pei causes the thick, wrinkly skin that typifies this breed. However, in some Shar-Pei dogs, the mucin deposition is excessive and “lakes” or pools of mucin develop. In these areas of mucin accumulation, there is a concomitant reduction in dermal collagen fibers and dilated lymphatic channels. These areas of the skin are fragile, and if traumatized, thick, stringy mucin exudes from the dermis.

### 17.2.1.3 EPIDERMOLYSIS BULLOSA (RED FOOT DISEASE)

*Epidermolysis bullosa* refers to a group of mechanobullous diseases, resulting in development of cutaneous blisters (bullae) in response to minor mechanical trauma. Blisters develop as a result of poor cohesion of the epidermis and dermis as a result of structural defects at the basement membrane zone. The structural defects are the result of mutations in genes responsible for the synthesis of a variety of structural components of this anatomic region of the skin and include abnormalities in keratin intermediate filaments, hemidesmosome-associated proteins, and anchoring fibrils, such as type VII collagen. The diseases vary in mode of inheritance, clinical manifestations, and anatomic location of the blisters. Animals affected with the diseases usually die because of their inability to obtain nourishment, loss of fluid and protein, and secondary infection leading to bacteremia. Epidermolysis bullosa has been reported in some breeds of sheep, horses, cattle, and dogs. Lesions can be present at birth or develop shortly thereafter and are located where epithelial surfaces are subjected to minor mechanical trauma, such as oral mucosa, lips, and extremities, including the coronary band. Shearing forces that normally cause no problem are sufficient to

## Pathologic Basis of Veterinary Disease, 4th Edition

cause injury in these animals. Microscopic lesions are those of an epidermal vesicular disease in which vesicles form in different locations (subepidermal, epidermal-dermal junction, intraepidermal) depending on the specific disease. The vesicles progress to ulcers, or if secondarily infected become pustules. As healing occurs, the reepithelization causes sloughing of the dried exudates over the ulcer, and the pustules dry to form crusts.

1161

1162

**Fig. 17-38 Collagen dysplasia, skin, dog.** **A**, The skin is hyperextensible. In this dog, the skin can be stretched more than the skin of a normal dog. **B**, The collagen bundles are irregular in size and shape and are arranged haphazardly. The abnormally functioning collagen is responsible for the hyperextensibility of the skin, which predisposes to tearing with normal handling and activity. H&E stain. **C**, Deeper level of the sample shown in [Fig. 17-38, B](#). Collagen bundles are stained blue. The variation in diameter and shape of the collagen bundles and their haphazard arrangement is accentuated with this stain. Masson's trichrome stain. (**A**, Courtesy Dr. Ben Baker, Washington State University. **B** and **C**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.2.1.4 EPITHELIOGENESIS IMPERFECTA (APLASIA CUTIS)

Epitheliogenesis imperfecta results from the failure of the stratified squamous epithelium of skin, adnexa, and/or oral mucosa to develop completely. The disease varies in severity and has been reported in most domestic species. It is the result of inherited genetic mutations in some species, but inheritance is not proven in other species. Additional information regarding the pathogenesis is not known. Without the protective covering of the stratified squamous epithelium, the underlying tissue is easily traumatized, can become infected, and bacteremia can develop. Grossly, lesions consist of sharply demarcated areas devoid of the epidermis and adnexa or mucosa, exposing the underlying red, moist dermis or submucosa. Lesions are located most often on the face, extremities, or mucous membranes, and can be small (1 cm) or involve extensive regions, such as the entire distal limb (Fig. 17-39). Small lesions can heal with scarring and not interfere with life. With extensive involvement, the entire skin can be affected, including hooves, ears, lips, and eyelids, and may result in abortion of the affected fetus. Animals born alive with extensive lesions usually die from infection or dehydration and electrolyte abnormalities from extensive fluid loss through nonepithelialized surfaces.

**Fig. 17-39 Epitheliogenesis imperfecta, calf.** **A**, Skin. Areas of epidermis over the extremities are missing (*arrows*). This condition is the result of inherited genetic mutations in some species, but inheritance is not proven in other species. **B**, Oral mucosa. Junction of normal and affected mucous membrane. Epithelium is present on the right (normal area) (*arrow*) but is abruptly missing on the left. The lack of germinal epithelium results in the failure of the epidermis, adnexa, or mucosal epithelium to develop completely. Skin, adnexa, and oral mucosa can be affected in this disease. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.1.5 CONGENITAL HYPERTRICHOSIS

Excessive growth of hair can be congenital or hereditary. Abnormally hairy fleece at birth develops in fine- and medium-wooled fetal lambs because of an in utero border disease virus infection. Fetal infection before 90 days of gestation results in an initial phase of retardation of follicular growth followed by an extended period of rapid growth of primary follicles. The altered growth rate of follicles results in production of larger, more heavily medullated primary wool fibers. The exact mechanism controlling the exaggerated growth of primary follicles is unknown. It has been speculated that reduction in number of the later developing secondary fibers could be the result of impaired nutrition because of placentitis. In addition to abnormal fleece, affected sheep have defective myelination of the brain and spinal cord, abnormalities of body conformation, poor growth, and reduced viability. Microscopically, primary follicles and wool fibers are enlarged and the number of the secondary follicles and wool fibers is reduced (see Morphology of the Skin, Hair Follicles and Fig. 17-7). In utero hypertrichosis can develop in lambs secondary to hyperthermia in pregnant ewes living in areas of high environmental temperature.

### 17.2.1.6 DERMATOSIS VEGETANS

Dermatitis vegetans is an inherited disorder of young pigs characterized by vegetating skin lesions, hoof malformation, and giant cell pneumonia. The condition is a simple autosomal recessive trait of Landrace pigs. The pathogenesis of lesion formation is unknown. Skin lesions can be present at birth but might not develop until 2 to 3 months of age. Lesions begin as erythematous papules on the ventral abdomen and medial aspect of the thighs and possibly the sides and back. The papules enlarge peripherally to form plaques with a depressed center filled with gray to brown-black granular brittle material. Each crusty plaque is sharply demarcated from normal skin by a hyperemic raised border. As lesions spread peripherally, they coalesce to form extensive horny, papilloma-like areas covered by black crusts. Foot and hoof lesions, if they occur, are always present at birth. Usually all digits, including accessory digits, on more than one limb are affected. The coronary region is markedly swollen and erythematous, and the skin is covered by a yellow-brown greasy material. The wall of the hoof is thickened by ridges and furrows parallel to the coronary band. Histologically, fully developed cutaneous lesions have marked orthokeratotic and parakeratotic hyperkeratosis, prominent irregular epidermal hyperplasia, intercellular edema, and intraepidermal pustules and microabscesses containing eosinophils and neutrophils. Affected piglets frequently die of secondary infection when skin lesions reach the typical papilloma-like stage (5 to 8 weeks of age) either from entrance of bacteria from skin lesions or a bacterial pneumonia complicating the giant cell pneumonia characteristic of this disease. Skin lesions begin to resolve if the pig survives.

1162

1163

### 17.2.2 DISORDERS OF PHYSICAL, RADIATION, OR CHEMICAL INJURY

#### 17.2.2.1 ACTINIC INJURY

Sunlight is composed of visible (400 to 700 nm), ultraviolet (100 to 400 nm), and infrared (700 to 20,000 nm) light rays. The portion of the ultraviolet (UV) light most damaging to the skin is ultraviolet B (UVB) and is in the range of 290- to 320-nm wavelength. However, photodynamic chemicals, if present in the skin, can chemically react with longer wavelengths, thus releasing energy and leading to the formation of reactive oxygen intermediates that initiate a chain of reactions resulting in cutaneous damage (photosensitization, phototoxicity). The amount of light reaching the skin is dependent on a variety of environmental and host factors, such as quantity of ozone, smog, and cloud cover (tend to absorb and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

scatter some of the UV rays), and the amount of pigment and hair (reflect or otherwise block UV rays from reaching the skin). Solar damage is more prevalent at high altitudes and at latitudes close to the equator, in areas with a high number of cloudless days, and in animals spending most of their time outdoors. The susceptibility of animal skin to actinic injury depends on the density of hair, degree of pigmentation, and thickness of the stratum corneum. Lesions generally develop in poorly haired and lightly pigmented skin.

### 17.2.2.1.1 Solar Dermatitis, Keratosis, and Neoplasia

The damage to skin by UV light can be acute (sunburn) or chronic (solar dermatitis, neoplasia). An early transient erythema may be due to the heating effect of the light rays and possibly to photochemical changes. The later developing erythema is called “sunburn erythema,” and the skin is warm, tender, and swollen. The pathogenesis of sunburn erythema may involve diffusion of inflammatory mediators, such as cytokines, from radiation-damaged keratinocytes, or from direct damage to endothelial cells of superficial dermal capillaries by UV light. One of the more influential alterations caused by exposure to UV light rays is the formation of thymidine dimers between pyrimidine bases of DNA. The damage can be easily and accurately repaired before the cell undergoes mitosis by an enzyme system that removes the damaged area and synthesizes a new strand of DNA. However, if the cell undergoes mitosis before the damage is repaired, a gap in the DNA strand is left at the location of the thymidine dimer. The gap is repaired by a postreplication repair method that is thought to be error-prone and may lead to mutations and the development of neoplasms. Factors that irritate the skin and increase the rate of cell division increase the number of cells repaired by the postreplication repair method and therefore can enhance development of neoplasms. UV radiation may also alter immunologic reactivity by inducing suppressor T lymphocytes, which favor growth of neoplastic cells. Preneoplastic and neoplastic lesions are common in chronically solar-damaged skin in domestic animals.

The lesions of sun-induced injury occur in all domestic animals. In cats, gross lesions occur where there is little or no hair and little pigment, particularly on external ear tips, eyelids, nose and lips, and are most severe in white cats. In dogs, lesions develop most commonly in nonpigmented, sparsely haired skin of the ventral abdominal, inguinal, and perianal areas (Fig. 17-40). Lightly pigmented young pigs are also susceptible, and the pinnae and tip of the tail can slough if injury is severe. In horses, lesions occur on the eyelids, nose, and around the prepuce. The eyelids of Hereford cattle are also prone to development of lesions. In lightly colored dairy goats, lesions can develop on the lateral aspects of the udder and teats. Grossly, lesions begin as erythema, scaling, and crusting. After years of exposure, the skin becomes wrinkled and thickened secondary to epidermal hyperplasia, hyperkeratosis, fibrosis, and in some species, elastosis. One or more papular or plaque-like foci covered with thick scale (hyperkeratosis)

1163

known as solar keratoses may develop, some of which progress to squamous cell carcinoma.

1164

Occasionally the hyperkeratosis is dense and compact, and resembles a “horn” (Fig. 17-40, B).

Hemangiomas and hemangiosarcomas have developed in the nonpigmented conjunctiva of dogs and horses and in the skin of dogs, cats, and a few goats. The cutaneous hemangiomas and

hemangiosarcomas are often seen on the abdomen and flanks of dogs that spend time resting in the sun.

The difference in type of neoplasm can be due in part to thickness of the epidermis, which influences the depth of penetration of the UV rays. UV light may also play a role in the development of melanomas in goats.

**Fig. 17-40 Solar dermatitis, skin, dog. A, Ventral abdomen and thorax.** The nonpigmented and sparsely haired skin is erythematous, has comedones and crusts, and is palpably thickened (*arrows*). The densely pigmented black spots are clinically unaffected, but lightly pigmented spots are affected. Comedones can rupture (furunculosis), releasing follicular contents that cause a foreign body inflammatory response and secondary bacterial infection. Clinically, the inflammation is prominent (erythema and furuncles) and can be misinterpreted as primary. Clinically, the distribution pattern of affected nonpigmented sparsely haired skin and unaffected haired or pigmented skin is supportive of the diagnosis of solar dermatitis. **B, Ventral abdomen.** Solar dermatitis with an actinic keratosis that has formed a cutaneous horn. Cutaneous horns are keratoses formed from multiple layers of compacted stratum corneum. They may arise from benign or malignant lesions in the epidermis (actinic keratosis, squamous cell carcinoma) or adnexa (infundibular keratinizing acanthoma). **C, The epidermis is thickened by acanthosis, and comedones (follicular hyperkeratosis) are present.** If comedones rupture, a large amount of endogenous foreign material (stratum corneum, hair shafts, and sebum) is released into the dermis, causing a foreign-body inflammatory response and bacteria that typically cause a secondary bacterial infection. H&E stain. (**A, B, and C, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.**)

Microscopically, in early UV-induced injury, the number of apoptotic cells (sunburn cells) scattered in the epidermis can be so numerous as to form a band of these cells along with intercellular edema, vacuolation of keratinocytes, and loss of granular cell layer. By 72 hours, hyperkeratosis, parakeratosis, and acanthosis are present along with dermal lesions of hyperemia, edema, perivascular mononuclear infiltrates, capillary endothelial cell swelling, and hemorrhage. Hyperkeratosis, parakeratosis, and acanthosis can persist, and pseudocarcinomatous hyperplasia (marked hyperplasia of the epidermis resulting in many branching and anastomosing epidermal ridges reaching down into the dermis) and dermal fibrosis can develop. The thickened epidermis with adherent compact and parakeratotic stratum corneum create the solar keratoses. Comedones (hair follicles dilated with a plug of follicular stratum corneum and sebum) develop in some dogs (Fig. 17-40, C). In some animals and in some anatomic locations, elastic tissue and collagen are damaged by solar radiation.

17.2.2.1.2

### Photosensitization

Photosensitization is a disorder caused by long-wavelength UV, or less frequently visible light, absorbed by a photodynamic chemical in the skin, or by a complex of photodynamic molecule and a biologic substrate, which results in a release of energy that produces reactive oxygen molecules, including free radicals. Generation of reactive oxygen molecules leads to mast cell degranulation and the production of inflammatory mediators, which causes damage to cell membranes, nucleic acids, proteins, and organelles. The photodynamic agent usually enters the dermis via the systemic circulation. However, direct contact and absorption of some photodynamic agents can result in localized contact photosensitization.

Photosensitization can occur in several forms. Type I or primary photosensitization, is often due to ingestion of preformed photodynamic substances contained in a variety of plants; thus herbivores are most commonly affected. The plants causing photosensitization usually contain helianthrone or furocoumarin pigments. The helianthrone pigments are red fluorescent pigments such as hypericin (found in *Hypericum perforatum* [St. John's wort]) and fagopyrin (found in *Fagopyrum esculentum* [buckwheat]). Photosensitization caused by furocoumarin pigments is due to the presence of psoralens, photodynamic agents found in a variety of plants including *Cymopterus watsonii* (spring parsely), *Ammi majus* (bishop's weed), and *Thamnosma texana* (Dutchman's breeches). Furocoumarin pigments also form phytoalexins, a group of compounds formed in plants in response to fungal infection or other injury and that inhibit or destroy the invading agent. The phytoalexins formed in fungus-infected parsnips and celery have caused phytophotocontact dermatitis when they are absorbed into the skin and react with UV light.

Primary photosensitization can also occur with the administration of drugs such as phenothiazine, which is converted to a photoreactive metabolite in the intestinal tract. This metabolite is usually converted to a nonphotoreactive compound in the liver by mixed function oxidases, but occasionally either the reactive metabolite bypasses the liver or mixed function oxidase activity in the liver is compromised or insufficient, and the reactive metabolite reaches the skin.

Type II photosensitization develops because of abnormal porphyrin metabolism, leading to the blood and tissue accumulation of photodynamic agents. These diseases usually are inherited as an enzyme deficiency, resulting in abnormal synthesis of photodynamic agents, including uroporphyrin and coproporphyrin. Examples include bovine congenital porphyria and bovine erythropoietic (hematopoietic) protoporphyria. Photosensitization due to abnormal porphyrin metabolism has also been reported in pigs and cats.

Type III or hepatogenous photosensitization is due to impaired capacity of the liver to excrete phyloerythrin, which is formed in the alimentary tract from the breakdown of chlorophyll. This is the most common type of photosensitization and occurs most commonly in herbivores, but any animal with generalized hepatic disease on a chlorophyll rich diet and that is exposed to sufficient solar radiation can develop hepatogenous photosensitization. Hepatogenous photosensitization occurs secondary to primary hepatocellular damage, inherited hepatic defects, or bile duct obstruction. Toxic plants, including but not limited to *Lantana camara* (lantana) and *Tribulus terrestris* (puncture vine), and mycotoxins such as sporidesmin are the most common cause of this type of photoensitization. Other plants that cause hepatic damage (such as those that contain pyrrolizidine alkaloids) can also contribute to the development of hepatogenous photosensitization.

Grossly, in photosensitization, lesions are located on areas of the body with nonpigmented skin and hair, and on parts of the body exposed to the sun, such as the face, nose, and distal extremities in horses. In cattle, lesions occur in white-haired areas and on the teats, udder, perineum, and nose. In sheep with heavy fleeces, lesions occur on the pinnae, eyelids, face, nose, and coronary band, but in shorn sheep, lesions can occur on the back. Sheep can have extensive edema of the head resulting in the synonyms of “swelled head” and “facial eczema.” Onset of lesions may take only hours and initially include erythema and edema, followed by blisters, exudation, necrosis, and sloughing of necrotic tissue. The microscopic lesions consist of coagulative necrosis of the epidermis and possibly follicular epithelium, adnexal glands, and superficial dermis. Subepidermal vesiculation can occur. Endothelial cells of the superficial, middle, and deep dermal vessels are swollen and necrotic, and fibrinoid degeneration and thrombosis can result in edema; infarction; sloughing of the epidermis, dermis, and adnexa; and secondary bacterial infection.

1165

17.2.2.1.3

### Photoenhanced Dermatoses

1166

Photoenhanced dermatoses are immune-mediated disorders that are aggravated by exposure to UV radiation, and include lupus erythematosus and dermatomyositis. Cytokines liberated from keratinocytes may play a role in photoenhancement. Clinical and histologic lesions are consistent with those of the specific disease process. Photoactivated vasculitis in horses may also represent a photoenhanced dermatosis; however, the cause and pathogenesis of this disorder are unknown. Sun exposure appears to trigger lesion development in some horses, but lesions do not always resolve with removal from sun exposure. Lesions typically develop in the white-haired extremities of horses, but rarely similar lesions occur in legs covered with dark hair. Lesions initially consist of well-demarcated erythematous, moist, crusted areas. More chronic lesions consist of plaques of epidermal acanthosis, hyperkeratosis, and crusting. Microscopically, lesions occur in small, thin-walled vessels of superficial dermal papillae. There is vascular dilation, endothelial degeneration, mild hyalinization of vessel walls, thrombosis, and perivascular edema and mild hemorrhage without significant inflammation.

17.2.2.2

### IONIZING RADIATION INJURY

Advances in the treatment of cancer in companion animals have made the possibility of radiation-induced skin injury more likely. Ionizing radiation consists of electromagnetic radiation (x-rays,  $\gamma$ -rays) and particulate radiation (electrons, neutrons, protons, etc.), and is most damaging to highly proliferative cells, such as those of the anagen hair matrix, but epidermal basal cells and vascular endothelial cells are also affected. Available radiation modalities offer differing degrees of tissue penetration and thus differing potential for tissue injury. Some forms of radiotherapy penetrate deeper tissues while sparing the skin, and

## Pathologic Basis of Veterinary Disease, 4th Edition

others are more concentrated in the superficial tissues or are preferentially absorbed by specific tissues. The type of radiation therapy, source, dose, intensity, and duration of exposure dictate the range of possible side effects. Ionizing photons disrupt chemical bonds in cells, leading to injury or cell death. Some cells are not lethally damaged, but sustain DNA damage to the extent that replication and/or replacement is not possible. The effects of radiation damage can be divided into acute and chronic forms.

Acute radiation injury to the skin is a result of damage to rapidly dividing cells. Damage is self-limiting and recovery is associated with rapid cell turnover. Clinical lesions of radiation dermatitis appear 2 to 4 weeks after exposure. Initially, there is erythema, pain, edema, and heat, followed several weeks later by dry or moist desquamation depending on the degree of injury. Histologically the lesions resemble a second-degree burn, with suprabasilar or subepidermal bullae formation, dermal edema with fibrin exudation, and a marked leukocytic infiltrate. Reepithelialization occurs over a period of 10 to 60 days. The damage sustained to germinal epithelium of hair follicles and sebaceous glands leads to alopecia within 2 to 4 weeks after exposure. Hair regrowth will follow over the next several months, but damage to sebaceous glands is not reversible and leads to permanent scaling manifesting histologically as hyperkeratosis. The chronic lesions of radiation injury are evident months to years after treatment and are primarily due to damage to the microvasculature. Chronic changes include pigmentary alterations (hyperpigmentation with lower doses and hypopigmentation with higher doses), leukotrichia (depigmentation of hair shafts because of loss of follicular melanocytes), dermal scarring, epidermal atrophy, and ulceration. The epidermis is thin, friable, and in some areas hyperplastic and can become neoplastic. Squamous cell carcinomas can develop in some sites of severe radiation damage because of sublethal DNA damage. Chronic nonhealing exudative ulcers can develop, but granulation tissue does not form. The dermis is fibrotic with atypical fibroblasts, telangiectasia, and possibly deep arteriolar changes. Endothelial swelling, necrosis, and thrombosis lead to occlusion and excessive endothelial proliferation, which, when combined with the effects of vascular leakage, leads to vascular collapse. This condition of progressive vessel abnormalities is referred to as obliterative endoarteritis and is known to form a "histohematic" (tissue-blood) barrier to surrounding tissue, leading to continued anoxia and nutrient shortage.

17.2.2.3

### CHEMICAL INJURY

Chemical injuries to the skin can result from local application directly onto the skin or from absorption of chemicals via the gastrointestinal tract and subsequent distribution to the skin. For a chemical to cause injury via local application, it must penetrate the hair and protective epidermal layers. Penetration is enhanced by physical damage to the stratum corneum, especially that caused by excessive moisture. Chemical injuries of the skin include contact irritant dermatitis (local application), systemically distributed chemicals, such as arsenic, mercury, thallium, iodine, and organochlorines and organobromines, and poisonings by fungal-contaminated plants and plants containing selenium, mimosine, and trichothecenes. Externally applied agents that produce irritant contact dermatitis induce cutaneous damage by altering the water-holding capacity of the epidermis or by penetrating the epidermis and directly damaging cells. Systemically absorbed and distributed chemical agents cause lesions by a wide variety of mechanisms, some of which are not known. An example is toxicity due to systemic absorption of some organochlorine and organobromine compounds, such as highly chlorinated naphthalenes, which were used as additives in lubricants for farm machinery, such as feed pelleting equipment. As a result, highly chlorinated naphthalenes were frequent feed contaminants. Toxicosis occurred most commonly in cattle, the most susceptible species, and was known as X-disease or bovine hyperkeratosis. Fortunately, this toxicosis is largely of historical interest as highly chlorinated naphthalenes have not been used in lubricants since the 1950s. Lesions of chlorinated naphthalene toxicity are due to the interference of the conversion of carotene to vitamin A, and result in vitamin A deficiency. Vitamin A is necessary for normal differentiation of

1166

1167

## Pathologic Basis of Veterinary Disease, 4th Edition

---

stratified squamous epithelium. Clinical lesions consist of alopecia and lichenified, fissured plaques of scale that spare only the legs. Histologic lesions consist of marked hyperkeratosis of the epidermis and follicles. Squamous metaplasia of the epithelial lining of the glands and ducts of the liver, pancreas, kidneys, and reproductive tract also develop.

### 17.2.2.3.1

#### Irritant Contact Dermatitis

There are two forms of contact dermatitis, one is immunologically mediated (see Selected Hypersensitivity Reactions, Allergic Contact Dermatitis), and the other is due to direct damage by irritant substances. Allergic contact dermatitis (immunologically mediated) requires prior sensitization to the offending agent. Most cases of contact dermatitis are nonimmunologic and are caused by direct contact with substances, such as body or wound secretions; application of drugs; or exposure to acids, alkalies, soaps, detergents, or irritant plants. These substances overwhelm the protective mechanisms of the skin and directly injure cells. It is important to realize that the two types of contact dermatitis can produce very similar histologic lesions, thus differentiation between immune-mediated and irritant contact dermatitis is largely dependent upon history, clinical signs, and anatomic distribution of the lesions. In dogs and cats, lesions of irritant contact dermatitis develop on the glabrous (sparsely haired) skin of the abdomen, axillas, flanks, interdigital spaces, perianal area, ventral tail, ventral chest, legs, eyelids, and feet. Horses develop lesions on the nose, ventrum, lower limbs, and where riding tack contacts the body, and on the perineum and caudal aspect of the rear legs. Grossly, erythematous patches, papules, and, rarely, vesicles develop, but self-inflicted trauma can lead to ulcers and crusts. Microscopically, lesions consist of spongiotic dermatitis, neutrophilic vesicopustules, and superficial dermal perivascular neutrophilic inflammation. Chronic lesions consist of epidermal hyperplasia, hyperkeratosis, and superficial perivascular inflammation. Lesions can be obscured by self-inflicted trauma, making histologic diagnosis difficult. Corrosive substances (strong acids or alkalies) can cause epidermal necrosis.

### 17.2.2.3.2

#### Injection Site Reactions

Injections of vaccines or therapeutic drugs into the subcutis can result in granulomatous nodules. Injected materials, such as adjuvant and other vaccine components are highly antigenic, and can incite a local and persistent immunologic response resulting in a palpable subcutaneous nodule. Histologic descriptions of the acute or subacute reactions to similar injected materials are not reported in the literature. Histologic changes represented by the palpable nodules at the site of previous vaccination consist of a localized area of deep dermal or subcutaneous necrosis containing foreign material thought to be adjuvant or vaccine components. The central zone of foreign and necrotic material is bordered by macrophages and multinucleated giant cells with a peripheral zone of lymphocytes and variable numbers of plasma cells and eosinophils (foreign body granuloma). Macrophages usually contain amphophilic granular foreign material. Lymphoid follicular development at the margins of these lesions can be extensive. Although many injection site lesions heal without serious consequences, in cats there is a causal relationship between postvaccination inflammation and development of fibrosarcomas, osteosarcomas, rhabdomyosarcomas, malignant fibrous histiocytomas, and chondrosarcomas. The antigen load and degree of persistent inflammation and eventual fibroblastic proliferation caused by subcutaneous vaccine administration are thought to be important factors predisposing to tumor development in cats. It is speculated that during tissue repair, fibroblasts or myofibroblasts are stimulated by the immunogenic substances in the vaccine reaction site and this, in combination with other factors such as oncogene alterations or unidentified carcinogens, leads to malignant transformation of cells. Tumor development can take months to years, with eventual neoplastic transformation of mesenchymal cells.

## Pathologic Basis of Veterinary Disease, 4th Edition

In small, often soft-coated, breeds of dogs, especially poodles, injection of killed rabies vaccine can result in localized lymphoplasmacytic panniculitis, subtle vasculitis, and localized ischemia leading to severe follicular atrophy in overlying dermis (Fig. 17-41) that is clinically apparent as a focal area of alopecia and hyperpigmentation. Immunofluorescence staining has identified rabies antigen in the vessels and epithelium of the hair follicles. A low-grade, immune-mediated vasculitis with resultant tissue anoxia leading to the atrophic changes in the adnexa has been suggested as the pathogenesis. Vascular lesions are characterized by hyalinization of the vessel wall, lack of endothelial cells, intramural karyorrhectic debris, and perivascular lymphocytic infiltrates. Rarely, small numbers of lymphocytes are found within the walls of affected vessels.

1167

1168

**Fig. 17-41 Rabies vaccine-associated alopecia, skin, haired, dog. A,** This type of alopecia (*arrows*) generally develops 3 to 6 months after vaccination. **B,** Note panniculitis (*P*) with lymphocytes, plasma cells, and histiocytes that has resulted from subcutaneous injection of killed rabies vaccine. Small, atrophic hair follicles (*arrows*) are in the dermis. H&E stain. (*A*, Courtesy Dr. Lynn Schmeitzel, College of Veterinary Medicine, University of Tennessee. *B*, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Injection site eosinophilic granulomas with necrotic centers have been reported to occur in horses 1 to 3 days after injections of various substances using silicone-coated needles. The reaction is suspected to be a form of delayed hypersensitivity.

### 17.2.2.3.3

#### Snake and Spider Bites (Envenomations)

The families Elapidae (coral snake) and Viperidae (rattlesnake, water moccasin, and copperhead) contain the majority of the poisonous snakes in the United States. The genera *Latrodectus* (e.g., black widow) and *Loxosceles* (e.g., brown recluse) are the most common venomous spiders causing cutaneous injury. Effects are dependent upon composition of the venom, individual victim response, anatomic location of the envenomation, and specific characteristics of the offending snake or spider, which can be influenced

## Pathologic Basis of Veterinary Disease, 4th Edition

---

by season of the year, geographic location, time since last inflicted bite or sting, depth of injury, etc. Different species of animals respond differently to the same venom.

Spider bites occur most often on the face and legs. The brown recluse spider (*Loxosceles reclusa*) is the spider most known to induce dermal necrosis, although there are a number of others. Brown recluse venom contains hyaluronidase and sphingomyelinase-D, which degrade tissue. A blister with a surrounding pale halo and more peripheral erythema characterizes initial reactions documented in human beings and some experimental animals. Necrosis and eschar formation occur within 5 to 7 days. Ulceration can be extensive. Histologically, there is hemorrhage and edema, neutrophilic vasculitis, and arterial wall necrosis. The epidermis and dermis undergo infarction that can extend into the subcutis and underlying muscle. Panniculitis can be present. Eventually, there is dermal scarring and replacement of the subcutis and muscle by hypocellular connective tissue. Brown recluse spider bites in human beings can also lead to massive hemolysis. Differentials include other venomous bites, vasculitis, slough due to iatrogenic injection of irritating substances, thermal burns, necrotizing fasciitis or other cutaneous infection, septic embolization, or trauma. Some putative spider bites (and possibly wasp and bee stings) in the dog develop as acute, painful, swollen areas on the dorsal or lateral nose that histologically consist of severe eosinophilic folliculitis and furunculosis (see Miscellaneous Skin Disorders, Nasal Eosinophilic Folliculitis and Furunculosis in Dogs) leading to the theory that these lesions are probably caused by hypersensitivity reactions to injected venom.

Snake bites are common in the dog, horse, and to a lesser degree cats and most often are inflicted on the head or legs. Snake venom contains various enzymes, proteins, peptides, and kinins. Of the five genera of venomous snakes in the United States, *crotaline* (rattlesnake, copperhead, cottonmouth, and others) venom contains the highest concentration of proteolytic enzymes. Snakebite envenomation produces pain, edema, and erythema that, if severe, are followed by necrosis and sloughing of tissue, and sometimes death of the animal. Variable systemic effects occur, including paralysis, coagulation disturbances, shock, increased capillary permeability, myocardial damage, rhabdomyolysis, and renal failure.

1168

17.2.2.3.4

### Ergot

1169

Ergot poisoning is due to the ingestion of toxic alkaloids produced by the fungus *Claviceps purpurea*. This fungus infects the seed heads of grasses and grains. The alkaloids, particularly ergotamine, cause direct stimulation of adrenergic nerves supplying arteriolar smooth muscle, resulting in marked peripheral arteriolar vasoconstriction and damage to capillary endothelium. Arteriolar spasm and damage to capillary endothelium lead to thrombosis and ischemic necrosis (infarction) of tissue. Cold temperatures increase the severity of the lesions. The species most commonly poisoned are cattle fed contaminated grain or cattle grazing pastures infected with the alkaloid-producing fungus. Lesions develop after about 1 week of consumption, and begin as swelling and redness of the extremities, particularly the hind legs. The tips of pinnae and tail are affected with dry gangrene (infarction) and can slough.

17.2.2.3.5

### Tall Fescue Grass

Lesions identical to those of ergot poisoning occur after the ingestion of tall fescue grass, a common pasture plant, infected by the endophytic fungus *Neotyphodium coenophialum* (formerly *Acremonium coenophialum*). Lesions develop about 2 weeks after ingestion of the toxic plant, and consist of necrosis

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(dry gangrene) of distal extremities. The ergot alkaloids, particularly ergovaline, are responsible for toxicity and act as peripheral vasoconstrictors.

17.2.2.3.6

### Selenium

Selenium poisoning is due to ingestion of plants that have accumulated toxic concentrations of selenium, or to an overdose of a selenium supplement. Some plants selectively accumulate selenium, regardless of soil selenium content. These selective accumulators (obligate accumulators; e.g., *Astragalus*, *Stanleya*) require selenium for growth, generally are not palatable, and are eaten only when other plants are unavailable. Many other plants (facultative accumulators; e.g., *Aster*, *Atriplex*) do not require selenium for growth but will accumulate toxic concentrations of selenium if grown in soil with high selenium concentrations. These facultative accumulator plants are commonly eaten by livestock, and more often are the cause of poisoning. The mechanism by which selenium is thought to exert its effects on the integument and appendages is through its competitive replacement of sulfur, which modifies the structure of keratin, a sulfur-containing molecule. Replacement of sulfur by selenium in other molecules can also contribute to toxicity. Acute or chronic selenium poisoning has developed in most domestic animals, although susceptibility to selenium poisoning varies with species, dosage, diet, rate of consumption, chemical form, and other factors. In acute poisonings, signs relate to involvement of multiple organ systems. Chronic selenium toxicity usually develops in livestock (cattle, sheep, and horses) consuming seleniferous forages. It occurs worldwide but is more frequent in Nebraska, Wyoming, and the Dakotas in the United States and in portions of Western Canada. Animals with chronic selenium intoxication are emaciated, have poor-quality hair coat, and have partial alopecia. Horses lose the long hair of the mane and tail, develop hoof deformities, and shed the hooves.

17.2.2.3.7

### Vetch Toxicosis and Vetchlike Diseases

Vetch toxicosis is most commonly seen as a syndrome characterized by dermatitis, conjunctivitis, diarrhea, and granulomatous inflammation of many organs. It occurs in cattle and to a lesser extent in horses after consumption of vetch-containing pastures. Hairy vetch (*Vicia villosa* Roth) is a cultivated legume used as pasture, hay, and silage in most of the United States and in other countries. Toxicity from vetch seeds is known to be a result of the presence of prussic acid. The cause of the granulomatous inflammation in this syndrome remains unclear. One proposed pathogenesis is that ingestion of vetch or another substance leads to antigen formation in the form of a hapten or a complete antigen that sensitizes lymphocytes and evokes the cell-mediated immune response upon repeat exposure.

Initial lesions in cattle consist of a rough coat with papules and crusts affecting the skin of the udder, teats, escutcheon (back of udder and perineum), and neck, followed by involvement of the trunk, face, and limbs. The skin becomes less pliable, alopecic, and lichenified. Marked pruritus leads to excoriations from self-induced trauma. The dermis has perivascular to diffuse infiltrates of monocytes, lymphocytes, plasma cells, multinucleated giant cells, and eosinophils. There is marked hyperkeratosis, and dermal and epidermal edema.

The clinical syndrome begins 2 or more weeks after consumption and consists of pruritic dermatitis, diarrhea (possibly bloody), and wasting. Morbidity is low and mortality is high. Holstein and Angus cattle, and cattle 3 years or older, are more often affected. Death in cattle occurs approximately 10 to 20 days after illness begins. At necropsy, yellow nodular infiltrates of mononuclear leukocytes are seen that disrupt the architecture of a wide range of organs but are most severe in myocardium, kidney, lymph nodes, thyroid, and adrenal glands. In cattle, other species of *Vicia* and additional compounds are

## Pathologic Basis of Veterinary Disease, 4th Edition

---

capable of inducing disease indistinguishable from vetch toxicity. These include feed additives, such as diureidoisobutane and citrus pulp.

Hairy vetch toxicosis in horses resembles that in cattle, except for the infrequent finding of eosinophils in the infiltrate and lack of heart involvement. Conditions very similar to vetch toxicosis have been 1169

reported in horses with no vetch exposure. These cases have been variably referred to as “idiopathic granulomatous disease involving the skin,” “systemic granulomatous disease,” “generalized granulomatous disease,” or “equine sarcoidosis.” Organ involvement is variable. Skin lesions include scaling, crusting, and alopecia on the face or limbs that progress to a generalized exfoliative dermatitis. Histologically the skin has multifocal, sometimes perifollicular to deep dermal nodules of granulomatous inflammation. These idiopathic conditions in the horse are fairly indistinguishable and should be considered “vetchlike disease” until more information is available. 1170

The diagnosis of vetch toxicity or vetchlike disease is a diagnosis by exclusion. It is made after review of the herd history and of character and distribution of the lesions. The combination of lesions is fairly distinctive.

### 17.2.2.3.8 Physical Injury

#### 17.2.2.3.8.1 Acral lick dermatitis

Acral lick dermatitis (lick granuloma, neurodermatitis) is a relatively common psychogenic dermatitis usually developing on an extremity (acral = extremity or apex) in dogs, and is caused by persistent licking or chewing. The cause is not known, but a mild sensory polyneuropathy that incites a sensation of pruritus or pain may be associated with lesion development. The constant licking and chewing of the skin is a form of repeated trauma that leads to the gross and histologic changes. Boredom can also play a role. Usually a single lesion develops in carpal, metacarpal, metatarsal, tibial, or radial areas. Grossly, lesions are circumscribed, hairless, and, sometimes, ulcerated (Fig. 17-42). Microscopically, there is compact hyperkeratosis and acanthosis of the epidermis and follicular epithelium. Ulcers are occasionally seen, the result of chronic irritation from licking. The dermis is thickened by fibrosis. Capillaries and some collagen fibers are oriented parallel to hair follicles, called “vertical streaking.” Sebaceous glands and hair follicles are hypertrophic, and there is perivascular and periadnexal plasmacytic dermatitis. Some lesions are complicated by secondary bacterial folliculitis and furunculosis.

Fig. 17-42 **Acral lick dermatitis, skin, leg, dog.** **A**, Chronic licking has resulted in an area of alopecia and a small dark ulcer in the alopecic area. Alopecia can be caused by mechanical removal of the hair or breakage of hair from licking, and in cases with secondary folliculitis, alopecia can also be due to follicular inflammation (folliculitis) and sometimes follicular rupture (furunculosis). Ulceration also can be caused by mechanical trauma to the skin surface. **B**, The epidermis is thickened by compact hyperkeratosis (*H*) and acanthosis (*A*), and the dermis is thickened by granulation tissue and fibrosis (scarring [*S*]). H&E stain. (*A and B*, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.2.2.3.9

### Pyotraumatic Dermatitis (Acute Moist Dermatitis, “Hot Spots”)

Pyotraumatic dermatitis, especially common in dogs, is secondary to irritation and is principally the result of self-inflicted trauma from biting or scratching because of pain or itching caused by allergies, parasites, matted hair, or irritant chemicals. Dogs with long hair and dense undercoats are predisposed, and lesions develop more commonly in hot humid weather. Flea bite dermatitis is a common predisposing cause, and lesions can coalesce to involve large portions of dorsal lumbar and thigh skin. Type I hypersensitivity reaction to flea bites leads to severe pruritus and self-trauma. Excoriated, moist skin is conducive to bacterial colonization. Grossly the lesions are hairless, red, exude fluid, and have circumscribed edges. Microscopically, affected dogs have either superficial erosive to ulcerative exudative dermatitis or a deeper suppurative folliculitis (pyotraumatic folliculitis, deep pyoderma). The pyotraumatic folliculitis lesions are considered to represent a deep pyoderma and develop more commonly on the cheek and neck of young golden retrievers, Saint Bernards, Labrador retrievers, and Newfoundland dogs. Biopsy is required to differentiate the more superficial pyotraumatic dermatitis from the deeper suppurative folliculitis.

1170

1171

### 17.2.2.3.10 Feline Ulcerative Dermatitis Syndrome

Feline ulcerative dermatitis syndrome is an uncommon disorder that may have more than one underlying cause. Previous injections and hypersensitivity are thought to initiate the syndrome in some, but not all, cats. The pathogenesis is not known, but self-trauma appears to significantly contribute to and perpetuate lesions. Lesions develop most commonly in the skin of the dorsal neck or interscapular regions, and grossly consist of a nonhealing ulcer with serocellular exudate that can mat the adjacent hair. Microscopic lesions consist of an ulcer covered by fibrinonecrotic crust. The dermis subjacent to the ulcer contains components of necrotic epidermis and adnexa intermixed with degenerate neutrophils. Adnexal effacement by fibrosis is seen in severe cases. Inflammation in adjacent and deeper dermis is variable, but often scant, and consists of a few neutrophils, eosinophils, and mixed mononuclear cells. Chronic lesions consist of acanthosis of bordering epidermis with a linear band of fibrosis beneath and parallel to the adjacent intact epidermis. In those cases attributed to previous vaccination, nodular lymphoplasmacytic to histiocytic panniculitis is present.

### 17.2.2.3.11 Callus

A callus is a raised, irregular, patch of thickened skin that develops because of friction, usually over pressure points on bony prominences or on the sternum ([Table 17-5](#)). Callosities can develop in all domestic animals, but are particularly common in giant breed dogs and in pigs kept on concrete or other hard flooring without adequate bedding. Secondary folliculitis, furunculosis, and ulceration can develop. Microscopically the epidermis and follicular epithelium are thickened by hyperkeratosis and acanthosis. Regular epidermal hyperplasia (rete ridge and dermal papilla interdigitation) also occurs. Comedones are present in some lesions. The follicular openings can be widened by excessive keratin. Dilated follicles can rupture (furunculosis), releasing bacteria, keratin proteins, and sebum, resulting in secondary pyoderma and a foreign body inflammatory response (callus pyoderma).

### 17.2.2.3.12 Intertrigo (Skin Fold Dermatitis)

Intertrigo is superficial dermatitis occurring on apposed skin surfaces, such as the facial fold (brachycephalic breeds), lip fold (breeds with large lips such as the Saint Bernard), body fold (Shar-Pei breed), vulvar fold (obese female dogs with a small vulva), and tail fold (dogs with corkscrew tails, such as English bulldogs) ([Fig. 17-43](#)). Intertrigo also occurs in cows with large pendulous udders and develops between the udder and the medial thigh (udder-thigh dermatitis). The cause and pathogenesis involve the presence of closely apposed skin surfaces, frictional trauma between the skin surfaces, accumulated moisture (from tears, saliva, cutaneous glandular secretions, or urine), and bacterial infection. The moisture and frictional trauma predispose to bacterial growth and subsequent infection. Early gross lesions of intertriginous dermatitis typically consist initially of erythema and edema. Later, pustules, ulcers, and crusts can develop. Late lesions in cows can be severe, with occasional sloughing of skin and subcutis. Microscopically, in early stages there is congestion and edema with early perivascular inflammation that progresses to a more diffuse band of inflammation in the superficial dermis, parallel to the epidermis, but often sparing the epidermal-dermal junction. Inflammatory cells include plasma cells, fewer lymphocytes, neutrophils, and macrophages. In more severe cases, there can be exocytosis of neutrophils into the epidermis, epidermal pustules, crusts, ulcers, and, in cows, necrosis that leads to sloughing of tissue. If the cause is corrected, early and mild chronic lesions heal without scarring (most cases). However, when there is ulceration or necrosis and sloughing of tissue (minority of cases), lesions heal by second intention with the formation of granulation tissue, wound contraction, and scarring.

### 17.2.2.3.13 Temperature Extremes

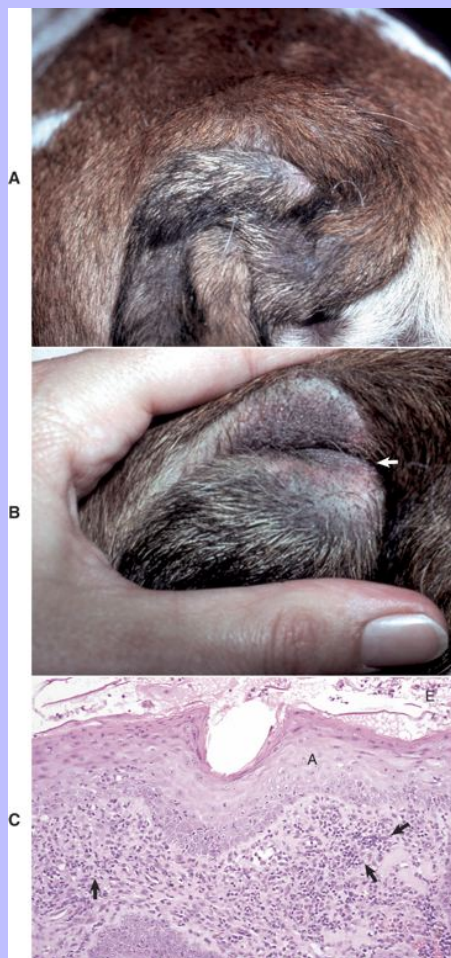

Exposure to cold temperatures causes different types of injury depending on the severity of the temperature extreme and length of exposure. The pathogenesis involves both direct freezing and disruption of cells and vascular damage, leading to tissue anoxia. In direct freezing, the initial injury results in the formation of extracellular ice crystals that damage cellular membranes, leading to cell death. As freezing continues, a shift in intracellular water to the extracellular space leads to cellular dehydration and increased intracellular sodium concentration and, eventually, to intracellular ice crystal formation. When intracellular ice crystals form and expand, the cell is mechanically and irreversibly damaged. Lesions are located in the extremities, such as the ear tips of cats, the scrotum of dogs and bulls, and the ear tips, tail, and teats of cattle. Grossly, lesions consist of infarction (dry gangrene) and sloughing of necrotic tissue.

In contrast, slow chilling produces vasoconstriction with endothelial and parenchymal cell damage. Subsequent secondary vasodilation causes increased vascular permeability followed by edema and neutrophilic inflammation. Exposure to more severe and persistent cold temperatures causes vasoconstriction, necrosis of vessels, increased blood viscosity, and coagulative necrosis of tissue because of anoxia. Cutaneous lesions due to cold temperatures are uncommon in well-nourished healthy animals but can develop in an animal recently moved from a warm to a cold climate or in neonates that are hypoglycemic or inadequately dried at birth.

1171

1172

**Fig. 17-43 Intertriginous inflammation (screw tail), skin, tail, dog. A,** “Screw tail,” English bulldog. Excessive skin folds around the tail cause friction and moisture accumulation, predisposing to bacterial growth. **B,** Intertriginous pyoderma, English bulldog. The skin fold (*arrow*) of the dog depicted in [Fig. 17-43, A](#) has been opened to expose the erythema, hyperpigmentation, and lichenification. **C,** Intertriginous dermatitis. The epidermis is acanthotic (*A*) and partially covered by fluid and cellular exudate (*E*), and there is inflammation composed of numerous plasma cells and fewer lymphocytes and neutrophils in the dermis (*arrows*). H&E stain. (*A and B, Courtesy Dr. Alexander Werner, Valley Veterinary Specialty Service. C, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.*)

Thermal burns are caused by exposure to excessive heat. Examples of heat sources include hot liquids, flames, friction, electricity, heating pads, blow dryers, drying cages, and lightning. Burns are categorized as partial (first- or second-degree) or full-thickness (third-degree). Longer exposure to lower temperatures is more damaging than shorter exposure to higher temperatures. Dry heat causes desiccation and carbonization, whereas moist heat causes coagulation of tissue. In less severe burns, damage is due to accelerated cellular metabolism, inactivation of enzymes, and vessel injury. In first-degree burns only the epidermis is affected, whereas in second-degree burns the epidermis and part of the dermis are damaged. In third-degree (full-thickness) burns, there is coagulation of the epidermis and all dermal components including connective tissue, blood vessels, and adnexa. Fourth-degree burns are similar to third-degree burns, but damage extends into the subcutaneous fascia and underlying tissue. Gross lesions of burns vary from erythema and edema due to capillary dilation and increased capillary permeability (first-degree burn) to vesicle formation as a result of fluid accumulation at the dermal-epidermal junction, which produces the “burn blister” (second-degree burn), to desiccation and charring of the epidermis, with underlying amorphous accretion of connective tissue representing the coagulated dermis and adnexa (third-degree burn). Microscopically, partial-thickness burns consist of coagulation necrosis of the epidermis, subepidermal vesicles as a result of accumulation of fluid from superficial capillaries (Fig. 17-18), necrosis of superficial portions of follicles and sebaceous glands, and degeneration of the subepidermal collagen. In partial-thickness burns, there is preservation of part of the epidermis or dermal portions of adnexa from which epithelial regeneration develops. Full-thickness (third-degree) burns are represented by coagulation of all components of the skin accompanied by acute inflammation. Subcutaneous vasculitis can be present. Partial-thickness burns involving the epidermis (first-degree burns) heal completely, as remaining epidermis and epithelium from adnexa reepithelialize the surface, and the dermis and adnexa are intact, so there is no scarring. However, partial-thickness burns that also involve the superficial dermis and superficial adnexa (second-degree burns) can result in superficial dermal scarring, but the adnexa are preserved. In full-thickness burns, over time histiocytes infiltrate the tissue, the necrotic tissue sloughs, and the defect is filled in by granulation tissue. Permanent scarring with loss of adnexa results unless skin grafts are performed, and if much of the body is affected, the lesions are life threatening because of fluid loss and possible sepsis from lack of the skin's protective barrier. In human beings, the prognosis in severe burn injury can be roughly calculated by adding the patient's age plus the percentage of the body with full-thickness burns (third-degree). If the total is 100, the likelihood of survival is low.

Moderate heat dermatosis (erythema ab igne) is an uncommon disorder reported in dogs and cats, and is caused by repeated chronic (weeks to months) exposure to moderate heat, too low to cause a thermal burn. Heat sources that have caused moderate heat dermatosis include heating pads, heated kennel mats, electric blankets, plant warmers, heat registers, and concrete driveways. When the heat source is in direct contact with the skin, conduction probably plays a role in mediating the injury, but the pathomechanism at the cellular level by which conductive heating causes moderate heat dermatitis has not been investigated. In dogs and cats, the cutaneous lesion distribution typically reflects chronic exposure to moderate heat during lateral or sternal recumbency. Clinical lesions consist of irregular areas of erythema, alopecia, and sometimes hyperpigmentation. Histologic lesions include keratinocyte karyomegaly, atypia, and degeneration, mixed dermal mononuclear inflammation, adnexal atrophy, and a variable number of wavy eosinophilic elastic fibers in the dermis. Hyperpigmentation is due to accumulation of melanophages and hemosiderophages in the dermis. Recall that exposure to moderate heat sources (e.g., heating pads on low temperature setting) can also cause thermal burns. Therefore lesions of thermal burns (e.g., coagulation of the epidermis) can coexist with those of moderate heat dermatosis.

### 17.2.3 MICROBIAL AND PARASITIC DISORDERS

Cutaneous infections develop when there is disruption in the defense mechanisms of the skin (see Host Defense Mechanisms against Injury). Predisposing factors to skin infections involve compromised epidermal barrier integrity caused by friction, trauma, excessive moisture, dirt, matted hair, chemical irritants, freezing or burning, irradiation, and parasitic infestation. Suppressed immune function resulting from inadequate nutrition, therapy with glucocorticoids, and other acquired or inherited immunologic abnormalities can also contribute to increased susceptibility to microbial and parasitic infections. Infectious agents enter the body via their specific portal of entry (see Portals of Entry into the Skin), which includes traversing the epidermal surface, entering via hair follicles or the ducts of glands, and migrating via nerves or sometimes via the hematogenous route.

#### 17.2.3.1 VIRAL INFECTIONS

##### 17.2.3.1.1 Poxviruses

Poxviruses are DNA epitheliotropic viruses that infect most domestic, wild, and laboratory animals and birds ([Table 17-8](#)). Dogs and cats are rarely infected with poxviruses, although infection with contagious ecthyma (parapoxvirus) has been reported in dogs, and cutaneous infection caused by a poxvirus of the orthopoxvirus genus (cowpox) has been reported in cats in Europe. There are major differences between different poxviruses and in the range of species they will infect, with some being species-specific and others zoonotic. Many poxviruses of animals, such as the contagious ecthyma parapoxvirus, can cause skin lesions in human beings. Poxviruses induce lesions by a variety of mechanisms. Lesions develop secondary to pox viral invasion of epithelium, by ischemic necrosis caused by vascular injury, and by stimulation of host cell DNA, resulting in epidermal hyperplasia. Hyperplasia may be explained by a gene, present in several poxviruses including molluscum contagiosum, whose product has significant homology with epidermal growth factor. Poxviruses also encode for functions that may counteract host defenses. These include genes related to those encoding the serpins (a superfamily of related proteins important in regulating serine protease enzymes that mediate kinin, complement, fibrinolytic, and coagulation pathways) and genes encoding antiinterferon activities. The severity of poxviral infection varies depending on whether the infection is localized or systemic and whether there are secondary infections. The sequence of the lesions are macule, papule, vesicle (varies in severity), umbilicated pustule, crust, and scar ([Fig. 17-33](#)). Histologically, pox lesions begin as epidermal cytoplasmic swelling and vacuolation, usually first affecting the cells of the outer stratum spinosum. Rupture of the damaged keratinocytes produces multiloculated vesicles, so-called reticular degeneration. The early dermal lesions include edema, vascular dilation, a perivascular mononuclear cell infiltrate, and a variable neutrophilic infiltrate. Neutrophils migrate into the epidermis and aggregate in vesicles to form microabscesses. Large intraepidermal pustules can form and sometimes extend into the superficial dermis. There is usually marked epithelial hyperplasia and sometimes pseudocarcinomatous hyperplasia of the adjacent epithelium. This contributes to the raised border of the umbilicated pustule. Rupture or drying of the pustule produces an inflammatory crust, often colonized on its surface by bacteria. Poxvirus lesions often contain characteristic intracytoplasmic eosinophilic inclusion bodies. These are single or multiple and of varying size and duration. Sheeppox and goatpox are the most pathogenic poxviruses, and infection causes significant mortality, especially in young animals as a result of systemic disease. Sheeppox and goatpox do not occur in the United States or Canada.

1173

1174

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-8 Viral Infections of the Skin

Virus	Diseases	Species Affected	Distribution
Parapoxvirus	Contagious pustular dermatitis Papular stomatitis Pseudocowpox	Sheep, goats, cattle; rarely dogs Cattle Milking cows; zoonotic	Cutaneous
Orthopoxvirus	Cowpox Vaccinia Horsepox* Equine papular dermatitis†	Some such as cowpox and vaccinia affect many species; others are more host specific	Cutaneous
Molluscipox	Molluscum contagiosum	Horses, rarely dogs	Cutaneous
Capripoxvirus	Sheeppox Goatpox Lumpy skin disease	Most species specific Cattle	Systemic
Suipoxvirus	Swine pox	Pigs	Cutaneous
Unclassified poxvirus	Ulcerative dermatosis of sheep	Sheep	Cutaneous
Bovine herpesvirus 2 (dermatotropic)	Bovine ulcerative mamillitis (bovine herpes mamillitis) Pseudo-lumpy skin disease	Cattle	Cutaneous
Bovine herpesvirus 4 (dermatotropic)	Bovine herpes mammary pustular dermatitis	Cattle	Cutaneous
Feline herpesvirus 1	Feline facial dermatitis and stomatitis	Cats	Cutaneous, oral, ocular, upper respiratory
Ovine herpesvirus 2‡ (in United States)	Malignant catarrhal fever	Cattle	Cutaneous, oral, systemic
Papillomavirus	Warts	All species	Cutaneous, oral, mucocutaneous
Papillomavirus	Fibropapilloma	Cattle	Cutaneous, genital
Papillomavirus	Sarcoid (fibropapilloma)	Horse, cat	Cutaneous
Papillomavirus	Bowen's-like disease	Cat, less in dog	Cutaneous
Papillomavirus	Pigmented epidermal plaques	Dog	Cutaneous
Picornavirus	Foot-and-mouth disease	Ruminants, pigs	Oral, cutaneous
Picornavirus	Swine vesicular disease	Pigs	Oral, cutaneous
Rhabdovirus	Vesicular stomatitis	Horses, cattle, pigs	Oral, cutaneous
Calicivirus	Vesicular exanthema	Pigs	Oral, cutaneous
Calicivirus	Feline calicivirus	Cats	Oral, cutaneous, systemic
Parvovirus	Porcine parvovirus	Piglets	Oral, cutaneous
Retrovirus	Feline leukemia virus  Feline immunodeficiency virus	Cats	Secondary skin infections; cutaneous horns with feline leukemia virus

\* Horsepox may be due to human or cattle orthopoxviruses.

† Virus not fully characterized.

‡ Indirect evidence of viral involvement.

## Pathologic Basis of Veterinary Disease, 4th Edition

17.2.3.1.1.1

### Contagious ecthyma

Contagious ecthyma (contagious pustular dermatitis, orf, sore mouth) is a common localized infection of young sheep and goats caused by a parapoxvirus with worldwide distribution. Less commonly, human beings, cattle, wild ungulates, and dogs are infected. Morbidity in lambs is usually great and, although mortality is usually low, it can approach 15% in lambs. Lesions are initiated by abrasions from pasture grasses or forage, begin at the commissures of the mouth, and spread to the lips (Fig. 17-44), oral mucosa, eyelids, and feet. Lambs can transfer the virus to the teats of ewes, and the lesions can spread to the skin of the udder. Contagious ecthyma is of economic importance due to weight loss in lambs that are reluctant to eat because of the pain associated with oral and perioral lesions. Pathogenesis of lesion formation and gross and microscopic features are consistent with the typical poxvirus lesions (see previous discussion and Fig. 17-33), except that the vesicle stage is very brief, the ulcer and crust stage persists and is clinically prominent, and the epidermis is markedly hyperplastic. Inclusion bodies are only briefly detectable histologically at the vesicular stage.

1174

1175

**Fig. 17-44 Contagious ecthyma, skin, lamb. A,** Note crusts around nose and lips. These lesions are the late stage of the disease, are formed after rupture of vesicles and pustules, and are responsible for the common name “scabby mouth.” **B,** Note the epidermal hyperplasia (acanthosis), ballooning degeneration, vesicle (V), and neutrophils accumulating in the vesicle, which will subsequently result in the formation of a pustule. Epidermal hyperplasia, upward movement of the pustule, and rupture of the vesicle or pustule contribute to crust formation as seen in Fig. 17-44, A. H&E stain. (A, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. B, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.2.3.1.1.2

#### Molluscum contagiosum

Equine molluscum contagiosum is a mildly contagious, self-limiting cutaneous infection in the horse caused by a poxvirus from the genera *Molluscipoxvirus* (molluscum contagiosum virus), a virus closely related to the human molluscum contagiosum virus. The equine lesions are small and often incidental and may be localized to the penis, prepuce, axillary and inguinal areas, and nose. The pathogenesis of lesion formation is typical of poxvirus infection (see previous discussion). Commencing as multiple, circular, smooth-surfaced, gray-white papules 1 to 2 mm in diameter, the lesions become umbilicated and develop a central pore from which a caseous plug is extruded. The microscopic lesions of molluscum contagiosum consist of well-demarcated foci of epidermal hyperplasia and hypertrophy that form invaginated lobules of the epidermis in the superficial dermis. Keratinocytes containing inclusions exfoliate through a pore that forms in the stratum corneum and enlarges into a central crater. The individual keratinocytes are markedly swollen and contain large intracytoplasmic eosinophilic inclusions, known as “molluscum bodies,” which can be identified histologically and in cytologic preparations. There is usually no dermal reaction. Rarely, molluscum contagiosum has developed in dogs.

### 17.2.3.1.1.3

#### Swinepox

Pox lesions in pigs are caused by the host-specific poxvirus *Suipoxvirus* (swinepox). Normally, swinepox is transmitted by contact, although transplacental infection has not been ruled out. The sucking louse *Haematopinus suis* often acts as a mechanical vector and assists infection by causing skin trauma. The virus persists in dried crusts from infected animals. The pathogenesis of lesion formation and morphology of the gross and histologic lesions are consistent with the typical pox infection. The gross lesions typically affect the ventral and lateral abdomen, lateral thorax, and medial foreleg and thigh. Occasionally, lesions on the dorsum predominate. Lesions can be generalized and rarely involve the oral mucosa, pharynx, esophagus, stomach, trachea, and bronchi. The erythematous papules usually transform into umbilicated pustules without a significant vesicular stage ([Fig. 17-45](#)). The inflammatory crust eventually sheds to leave a white scar. The disease occurs worldwide and is endemic to areas of intensive swine production. The disease affects young, growing piglets and is mild with very low mortality.

1175

Fig. 17-45 **Swine pox, skin, piglet.** **A**, Note the four umbilicated pustules in the abdominal skin. **B**, Note keratinocytes with ballooning degeneration and eosinophilic cytoplasmic inclusion bodies. Ballooning degeneration develops before vesicle formation. H&E stain. (**A and B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

17.2.3.1.1.4

#### Cowpox

Cowpox virus infections occur rarely in cattle in the United Kingdom and other areas of Europe. There is increasing evidence that small wild rodents (i.e., mice, squirrels, voles) serve as a reservoir for infection, and that cattle, cats, and rarely other mammals become infected through contact with the wild rodents. Cutaneous infections in cattle usually develop on the teats and udder of cows and on the muzzle of suckling calves. Lesions follow the typical sequence of cutaneous pox viral infections. In cats, poxvirus infection is uncommon and usually occurs in outdoor cats living in rural areas, presumably because these cats hunt and have contact with rodents harboring the poxvirus. Primary cutaneous lesions typically develop on the face, neck, or forelegs and consist of an ulcerated or crusted macule or plaque. Lesions can develop into deep ulcers that heal with granulation tissue or less commonly develop into abscesses or cellulitis. Rarely oral or mucocutaneous junctional areas are

## Pathologic Basis of Veterinary Disease, 4th Edition

---

affected. Additional secondary cutaneous lesions can develop within about two weeks after viremic distribution to other cutaneous sites and less commonly to the upper or lower respiratory tract. The microscopic lesions are sharply demarcated, often deep ulcers covered by fibrinonecrotic exudate. Intracytoplasmic inclusion bodies in keratinocytes or follicular or sebaceous glandular epithelial cells help establish the diagnosis.

17.2.3.1.2

### Herpesviruses

Herpesviruses are DNA viruses that only occasionally produce cutaneous lesions ([Table 17-8](#)). Cutaneous lesions have rarely been reported in nondermatotropic herpesviruses infections, such as infectious bovine rhinotracheitis (bovine herpesvirus 1) and equine coital exanthema (equine herpesvirus 3), and in cats with feline herpesvirus 1 infection. Two dermatotropic herpesvirus infections with economic importance are bovine herpesvirus 2 and bovine herpesvirus 4. Herpesviruses can be latent, with inactive virus persisting in tissue such as the trigeminal nerve ganglia. It is speculated that up to 80% of adult cats recovered from feline herpesvirus 1 infection as kittens or young cats have latent herpesvirus 1 infections. During times of stress, the virus is reactivated and lesions can recur. Herpesviruses infect epithelial cells and replicate in the nucleus, leading to lysis of nuclear contents. As immature viral particles enter the cytoplasm, there is degeneration of cytoplasmic organelles, accumulation of cytoplasmic lipid, and precipitation of protein. Death of keratinocytes leads to spread of virus to neighboring cells, leading to rapid necrosis of focally extensive areas of the epidermis. Gross lesions consist of vesicles that rupture to form ulcers that are then covered by crusts. Microscopic lesions in herpesvirus infections depend on the stage, but early degenerative changes include ballooning and reticular degeneration, the sequelae of degeneration of epidermal cells and acantholysis. Syncytial cells may be seen. Intranuclear inclusions develop, but because of rapidly developing necrosis may not be found except at the margins of ulcers. The appearance of the viral inclusions varies with the specific herpesvirus. Some herpesviruses produce large, hyaline amphophilic inclusions that fill the nucleus (feline herpesvirus 1), whereas others (bovine herpes mammillitis) produce typical Cowdry type A inclusions, which are also intranuclear but smaller and eosinophilic.

17.2.3.1.2.1

### Bovine herpesvirus 2

Bovine herpesvirus 2, a dermatotropic virus (Allerton virus), can cause generalized disease (pseudo-lumpy skin disease) or, as seen in the United States, localized infection of the teat called bovine ulcerative mammillitis (bovine herpes mammillitis). Mammillitis is inflammation of the teat or nipple. Localized infection occurs more commonly in lactating dairy cows but can develop in beef cows, pregnant heifers, and suckling calves. Trauma is implicated in the pathogenesis because normal skin is resistant to viral penetration. The pathogenesis of lesion formation was discussed earlier. Bovine ulcerative mammillitis is of economic importance because of decreased milk production and secondary bacterial mastitis. Lesions develop on the teats and skin of the nearby udder or occasionally the perineum. Suckling calves develop lesions on the muzzle (nose).

1176

1177

17.2.3.1.2.2

### Bovine herpesvirus 4

Bovine herpesvirus 4 (bovine herpes mammary pustular dermatitis) causes a similar but milder disease than the localized form of bovine herpesvirus 2.

### 17.2.3.1.2.3

#### Feline ulcerative facial dermatitis and stomatitis

Feline herpesvirus 1 is an uncommon cause of ulcerative, often persistent, facial dermatitis or stomatitis in cats of various ages and sexes. Glucocorticoid therapy or stresses, such as overcrowding, are thought to play a role in lesion development. Most lesions develop under circumstances suggesting reactivation of latent herpesvirus infection. The pathogenesis is typical of that described for herpesviruses in the previous section. Gross lesions are ulcerative and crusted ([Table 17-5](#)). Histologically, there is extensive necrosis of the epidermal, follicular, and sometimes sebaceous gland epithelium accompanied by prominent mixed dermal inflammation that frequently includes numerous eosinophils. Follicular epithelium can be destroyed, and free keratin in the dermis is associated with eosinophils and foci of eosinophil degranulation bordering collagen fibers and collagen degeneration. Large amphophilic or hyaline intranuclear inclusions are present in the surface and adnexal epithelium. Inclusion bodies are often easily overlooked, variable in number, and sometimes present in small rafts of epithelial cells surrounded by necrotic debris. The lesions are different from those previously reported in domestic cats in that they persist and are limited to the skin of the face or oral mucosa and often have significant eosinophilic inflammation. The inflammation in feline herpesvirus dermatitis overlaps with that of the hypersensitivity reactions, including mosquito bite hypersensitivity, and also with that of eosinophilic ulcers, thus warranting close scrutiny of eosinophilic necrotizing cutaneous lesions for intranuclear inclusion bodies.

### 17.2.3.1.3

#### Papillomaviruses

Papillomaviruses are typically species- and site-specific pathogens that infect the squamous epithelium and cause benign proliferative masses and less commonly malignant tumors. All domestic animals are affected by one or more papillomaviruses ([Table 17-8](#)). Papillomaviruses cause lesions by two different mechanisms. In some cells, infection elicits increased activity, mitosis, and proliferation that lead to the gross and histologic changes of hyperplasia and hyperkeratosis (nonproductive infection). The hyperplastic cells are considered transformed. In other cells, infection leads to degeneration, virion production within the cell nucleus, and eventual cell death (productive infection). The effect the papillomavirus has on the cell (i.e., proliferation or virion production leading to cell death) is dependent on the way the viral genome is inserted into the host cell genome and on the stage of the cell cycle of the host cell at the time of infection. In the epidermis, virion production is limited to cells of the suprabasilar layer. Clinical and histologic lesions are diverse. The most common type of cutaneous papillomavirus infection (papilloma, wart, cutaneous papillomatosis) consists of clinical lesions that are alopecic, flat, or papilliferous benign masses ([Fig. 17-46](#)). Histologically, stratified squamous epithelium is covered by thickened orthokeratotic or parakeratotic keratin, is acanthotic, and has elongated epidermal-dermal interdigitations. The epidermis rests on a collagenous core. In some papillomas, keratinocytes, especially of the upper stratum spinosum, are swollen with amphophilic cytoplasm and have an eccentric nucleus and a perinuclear halo; these keratinocytes are termed “koilocytes” (meaning hollow or concave). Keratohyalin granules are irregular. Also, pale basophilic intranuclear inclusion bodies, located in degenerating cells in the outer layers of the stratum spinosum and granulosum in which virion production is taking place, occur in some but not all papillomas. Papillomas spontaneously regress, and in regressing stages, there is reduced epidermal hyperplasia, increased proliferation of fibroblasts, deposition of collagen, and infiltration of T lymphocytes at the epidermal dermal interface.

In cats and horses, papillomavirus infection also causes development of cutaneous fibropapillomas (sarcoids). These are flat, verrucous, or nodular masses in which the proliferation of dermal fibroblasts is

## Pathologic Basis of Veterinary Disease, 4th Edition

the prominent feature, often surpassing that of the epidermal hyperplasia (Fig. 17-47). Equine sarcoids are caused by a nonproductive infection of bovine papillomavirus and are locally aggressive, nonmetastatic fibroblastic skin tumors of horses, mules, and donkeys. They are the most common skin tumor of horses, accounting for up to 30% of tumors, and occur in any breed, sex, or age. Young adult horses 3 to 6 years of age are most commonly affected. Sarcoids frequently develop in areas subjected to trauma or at sites of wounds 6 to 8 months after wound healing, and develop anywhere but are most common on the head, legs, and ventral trunk. They can be single or multiple. The tumors are classified according to their gross appearance as verrucous, fibroblastic, mixed, or occult. The verrucous type is a small wartlike growth, usually measuring less than 6 cm in diameter, with a dry, rough surface and variable alopecia. The fibroblastic type of sarcoid is more variable in appearance and can range from a well-circumscribed firm nodule with intact surface to a large mass, greater than 25 cm in diameter, with an ulcerated surface prone to hemorrhage, and resembling exuberant granulation tissue. The mixed type is a transitional form in which a verrucous sarcoid becomes a fibroblastic type as a result of trauma or biopsy. The occult form consists of a slow-growing, slightly thickened area of skin with slight surface roughening and alopecia that remains static for a long period.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Histologically, sarcoids are typically biphasic tumors composed of both epidermal and dermal components; however, the epidermal component may be minimal or absent in some tumors, especially those with extensive ulceration. When the epidermis is intact, hyperkeratosis, parakeratosis, and acanthosis with thin rete pegs extending deep into the dermis are common features. The dermal component consists of fibroblasts and collagen in various proportions. The fibroblasts have plump nuclei, and nucleoli may be prominent. The mitotic index is usually low. Fibroblasts at the dermal-epidermal junction are frequently oriented perpendicular to the basement membrane in a “picket fence” pattern, which is a distinctive histologic feature seen in most sarcoids. The cells are arranged in whorls, interlacing bundles, or haphazard arrays of variable density. Tumor margins are typically indistinct and adequacy of excision is frequently difficult to determine. Spontaneous remission can occur after several years in up to 30% of cases. The tumors are characterized by a high rate of recurrence, up to 50%, following surgical excision. Bovine papillomavirus DNA has also been identified in feline fibropapillomas (sarcoids).

Papillomavirus infection may also contribute to the development of another syndrome in cats and less often in dogs termed, “multicentric squamous cell carcinoma in situ” (Bowen's-like disease). Although 1178  
not all the factors contributing to lesion formation have been documented, papillomavirus DNA has been 1179  
identified in these lesions in cats, suggesting a nonproductive infection promotes the epithelial hyperplasia characteristic of this disease. Multicentric squamous cell carcinoma in situ clinically consists of sharply demarcated single, or more often multiple, scaly verrucous or irregular plaquelike lesions 0.5 to 3.0 cm in diameter. Histologically the epidermis and follicular infundibular epithelium are thickened by proliferation of basal keratinocytes that tend to stream together, providing a “windblown” appearance to the epidermis. Nuclei are often varied in size with hyperchromatic nuclei, large nucleoli, and numerous mitoses, some of which are located above the basal layer. The basement membrane, at the time of histologic examination, is intact. Most lesions remain as “in situ” carcinomas indefinitely, but an occasional lesion has progressed to invasive basal cell carcinoma or invasive squamous cell carcinoma.

Fig. 17-47 **Sarcoid, skin, horse.** **A**, Equine sarcoid, face. The irregular multinodular mass is present on the ventrolateral periorcular skin. **B**, Sarcoid. The sarcoid consists of an epidermal and dermal component. The hyperplastic epidermis has thin rete pegs that extend into the dermis. The dermis is thickened by proliferating fibroblasts and collagen. H&E stain. (**A**, Courtesy Dr. Helen Power, *Dermatology for Animals*. **B**, Courtesy Dr. Pamela E. Ginn, *College of Veterinary Medicine, University of Florida*.)

Pigmented epidermal plaque (epidermodysplasia verruciformis) is caused by papillomavirus infection in certain breeds of dogs (miniature schnauzers, pugs, and Shar-Peis) or in other breeds of dogs that are immunosuppressed. Clinical lesions occur most commonly on the ventral abdomen, groin, ventral thorax, or neck, and consist of variably irregular, pigmented macules, or plaques. Histologically the lesions are sharply demarcated, hyperkeratotic foci, or plaques with pigmented, acanthotic epidermis, and large keratohyalin granules. These pigmented epidermal plaques do not regress, are slowly progressive, and occasionally develop into a squamous cell carcinoma.

### Other Viruses

Cutaneous lesions are seen with foot-and-mouth disease (picornavirus), vesicular stomatitis (rhabdovirus), swine vesicular disease (picornavirus), vesicular exanthema (calicivirus), and malignant catarrhal fever (herpesvirus) (see [Chapter 7](#)) ([Table 17-8](#)). Feline leukemia virus (FeLV) can cause the development of lymphoma and fibrosarcoma. A few cats with FeLV infection have developed dermatitis characterized by epidermal and follicular acanthosis with epidermal giant cells, dyskeratosis, necrosis, and ulceration. In addition, a few FeLV-infected cats have also developed one or more localized areas of marked compact hyperkeratosis of the footpads that clinically resemble “horns” (cutaneous horns). In immunoperoxidase-stained sections, the hyperplastic epidermis in cases with epidermal giant cells is strongly positive for FeLV. Both FeLV and feline immunodeficiency virus (FIV), because of their immunosuppressive capabilities, can cause cats to be susceptible to chronic skin infections, including abscesses, paronychia, and demodicosis.

Feline calicivirus, usually the cause of upper respiratory infection and oral ulcers with high morbidity but low mortality, rarely produces cutaneous ulcers. More recently, virulent systemic strains of feline calicivirus with mortality rates between 30% and 60% have been described. These strains cause alopecia, cutaneous ulcers, and subcutaneous edema. The pathogenesis involves lysis of epithelial cells of the epidermis, follicles, oral mucosa, bronchioles, alveoli, and exocrine pancreas, in addition to lysis of endothelial cells. The lysis of epithelial and endothelial cells leads to necrosis, edema, fibrin exudation, and thrombosis from vascular injury, and release of inflammatory mediators from damaged cells. Clinical lesions include ulcers of the nose, lips, pinnae, feet, and oral mucosa, variable alopecia of limbs and ventrum, and subcutaneous edema, especially of the limbs and face. Systemic signs of fever, anorexia, icterus, red and swollen conjunctival mucosa, and nasal or ocular discharge are present. The most consistent microscopic lesions are epithelial necrosis with subsequent ulceration of the skin and oral and nasal mucosa. Vascular injury consists of edema, microthrombosis, and fibrin exudation. Broncho-interstitial pneumonia and necrosis of the liver, pancreas, spleen, and lymph nodes are present in some cats. In contrast to infection with the more common and less virulent field strains of feline calicivirus, the systemic virulent strains cause more severe disease in adult cats than kittens.

1179

1180

### BACTERIAL INFECTIONS

The portals for entry of bacteria into the skin include pores (follicular openings), hematogenous spread, or direct entry through damaged skin. Cutaneous bacterial infections vary in location (e.g., epidermis, dermis, subcutis, adnexa, or systemic), morphology (e.g., pyogenic, granulomatous, or necrotizing), distribution (e.g., focal, multifocal, regional, mucocutaneous, haired skin, or interdigital), and severity (e.g., mild and asymptomatic to severe with systemic signs). The variation is due to the specific organism involved, predisposing or coexisting factors, and host-immune response. The so-called superficial and deep bacterial infections are frequently pus-producing infections (pyogenic) and are thus referred to as pyodermas. In contrast, bacterial granulomas are characterized by an abundance of macrophages and are usually caused by traumatic implantation of bacteria that generally are saprophytes of low virulence. Systemic bacterial infections or localized infection with toxin-producing bacteria are often most severe because of vascular damage or the presence of endotoxins or exotoxins that have systemic consequences. The most common bacterial infections of the skin are listed in [Box 17-8](#).

### 17.2.3.2.1 Superficial Bacterial Infections (Superficial Pyodermas)

These infections involve the epidermis and the upper infundibulum of hair follicles, usually heal without scarring, and usually do not involve the regional lymph nodes. Gross lesions include erythema, alopecia, papules, pustules, crusts, and peripheral expanding rings of scale also called “epidermal collarettes” (Table 17-5). The early microscopic feature of superficial bacterial infection that involves the epidermis is intraepidermal pustular dermatitis. The intraepidermal pustules are fragile and can rupture, leading to crust and superficial scale formation. The major microscopic feature of superficial bacterial infection that involves the follicles is superficial suppurative luminal folliculitis. The cellular infiltrate in and around hair follicles plus dermal congestion and edema correspond to the clinically evident papules and follicularly oriented pustules. Follicular injury leads to alopecia. Although gram-positive cocci, such as *Staphylococcus* sp., are usually the cause of the superficial bacterial infections, the bacteria are not always microscopically demonstrable. Predisposing factors, such as allergy, seborrhea, immune deficiency, and other causes of follicular inflammation or dysfunction often play a role.

Papillomatous digital dermatitis

17.2.3.2.1.2

### Superficial pustular dermatitis (impetigo)

This infection is observed in dogs, cats, piglets, cows, does, and ewes and is caused by coagulase-positive *Staphylococcus* sp. in association with such predisposing factors as cutaneous abrasions, viral infections, increased moisture, and poor nutrition. *Staphylococcus intermedius* is the most frequent cause of the condition. This organism produces proinflammatory mediators, such as protein A, which binds to the Fc receptor of IgG, leading to the activation of complement and the eventual production of substances chemoattractant for leukocytes initiating a chain of events that mediate inflammation and lead to tissue damage. Older dogs with immunosuppression, usually because of hyperadrenocorticism, may develop a bullous impetigo. In cows, does, and ewes, lesions are predominantly on the udder. In kittens, the dorsum of the neck and shoulders are affected because of overzealous “mouthing” by the queen; *Streptococcus* sp. and *Pasteurella* sp. are the more common bacterial isolates as these are part of the oral flora. Gross lesions consist of pustules that develop into crusts, principally in nonhaired skin (except in kittens). The microscopic lesion is a nonfollicular neutrophilic subcorneal pustule. In bullous impetigo, the lesions are more severe with large interfollicular flaccid pustules that when ruptured lead to more extensive loss of the superficial epidermis. Dermal inflammation in impetigo is minimal.

1180

1181

17.2.3.2.1.3

### Superficial spreading pyoderma

Superficial spreading pyoderma is a common, often pruritic, superficial bacterial infection in dogs caused by *Staphylococcus intermedius*. The pathogenesis is poorly understood. Initial studies revealed that dogs with the superficial spreading variety of pyoderma more frequently had IgE antibodies directed against staphylococci than dogs with other forms of staphylococcal pyoderma, suggesting that bacterial hypersensitivity might play a role. In addition or alternatively, proinflammatory mediators, including protein A as described earlier for impetigo, might contribute directly. Clinical lesions are most frequently recognized in the glabrous ventral thoracic and abdominal skin, but can affect the haired skin of the dorsal and lateral trunk as well. Early clinical lesions include erythematous macules, papules, and transient pustules. Older clinical lesions include epidermal collarettes, crusts, alopecia, and hyperpigmentation. Early microscopic lesions are superficial, spongiotic epidermal pustules that rapidly crust and form basophilic debris, often with cocci, on the surface of the epidermis. This basophilic debris can dissect peripherally (laterally) between the epidermis and stratum corneum and is thought to form the rim of scale that clinically represents the epidermal collarette. Occasionally, superficial spreading pyoderma can originate from superficial folliculitis where follicular pustular formation is minor and epidermal collarette formation more prominent. Dermal lesions include superficial perivascular to interstitial accumulations of neutrophils, eosinophils, and mixed mononuclear cells. Some dogs have neutrophilic vasculitis involving superficial venules possibly due to immune-complex deposition, a feature suggesting a hypersensitivity response to bacterial antigens. Dermal congestion and edema are usually present.

17.2.3.2.1.4

### Mucocutaneous pyoderma

Mucocutaneous pyoderma is a putative bacterial infection of mucocutaneous junctional skin in dogs. A variety of breeds are affected, but the German shepherd breed is thought to be predisposed. The pathogenesis is unknown. Lesions consist of erythema, depigmentation, crusting, and in severe cases ulceration. Lesions are most common on mucocutaneous skin of the lips, but mucocutaneous skin of prepuce, vulva, and anus can be affected. Histologic lesions include a dense band of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

lymphoplasmacytic inflammation at the epidermal dermal junction (lichenoid inflammation), typically without basal cell degeneration. Other features include spongiosis and cellular exocytosis into the epidermis, neutrophilic pustular crusts, and folliculitis of adjacent follicles. Over time pigmentary incontinence develops. Although classic cases are said not to have basal cell degeneration, there is interface inflammation obscuring the epidermal-dermal interface of some cases of mucocutaneous pyoderma, preventing definitive differentiation from discoid lupus erythematosus.

17.2.3.2.1.5

### Dermatophilosis (streptothricosis)

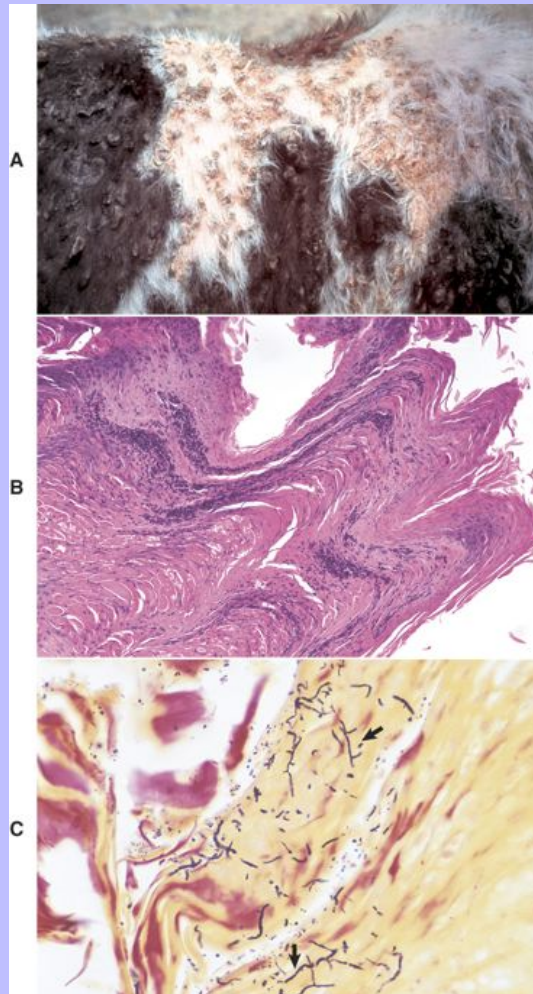

This infection, caused by *Dermatophilus congolensis*, is characterized by crusty cutaneous lesions (Fig. 17-48), and occurs in cattle, sheep, and horses more often than dogs, cats, pigs, and goats. The bacterium is transmitted by carrier animals and is more common in tropical and subtropical countries and during wet weather. Lesions tend to develop on the dorsum of the back and distal extremities and after epidermal irritation from ectoparasites, trauma, or prolonged wetting of the skin, hair, or wool, which allows penetration of the damaged epidermis by the *Dermatophilus* “zoospore.”

The bacterium grows in the outer root sheath of the hair follicle and superficial epidermis and produces gram-positive filamentous branches that subdivide longitudinally and transversely (Fig. 17-48). These bacteria stimulate an acute inflammatory response in which neutrophils migrate from superficial vessels into the dermis and through the epidermis to form intraepidermal microabscesses. The inflammation inhibits further penetration of the bacterium. However, residual bacterial organisms subsequently invade the newly regenerated epidermis. Thus repeated cycles of bacterial growth, inflammation, and epidermal regeneration result in the formation of the multilaminated pustular crusts. Grossly, lesions consist of papules, pustules, and thick crusts that can coalesce and mat the hair or wool (Fig. 17-48). The microscopic lesions consist of hyperplastic superficial perivascular dermatitis with multilaminated crusts of alternating layers of keratin and neutrophils covering the skin surface. Samples of crusts obtained by biopsy are necessary to identify organisms and make a definitive diagnosis.

1181

1182

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.2.3.2.1.6

### Exudative epidermitis of pigs (greasy pig disease)

Exudative epidermitis, caused by *Staphylococcus hyicus* (*hyos*), is an acute, often fatal, dermatitis of neonatal piglets but a mild disease in older piglets. Predisposing factors include cutaneous lacerations and poor nutrition. *Staphylococcus hyicus* (*hyos*) produces an exotoxin, called “exfoliatin,” which binds to filaggrin in the keratohyalin granules of the stratum granulosum in the epidermis. This reaction probably causes focal erosion of the stratum corneum. Dermatitis and brownish exudates develop around the eyes, pinnae, snout, chin, and medial legs and spread to the ventral thorax and abdomen, giving the animal an overall “greasy” appearance (Fig. 17-49). The lesions rapidly coalesce and become generalized, resulting in greasy, malodorous exudates covering an erythematous skin. If piglets survive, the exudate hardens, cracks, and forms fissures. Subacute disease develops gradually in older piglets, and lesions are generally localized to the skin of the face, pinnae, and periocular regions. Grossly the epidermis is thickened with scaling. The early histopathologic lesion is subcorneal pustular dermatitis, which extends to the hair follicle, resulting in superficial suppurative folliculitis. In the fully developed lesion, the epidermis is hyperplastic and has thick crusts of keratin, microabscesses, and cocci. The term exudative epidermitis is descriptive of this condition as the inflammatory changes largely involve the epidermis, and there is an accumulation of exudates on the surface. The dermis is congested and edematous. In the early stages, the dermatitis is superficial and perivascular with neutrophils and eosinophils, and in the later stages is perivascular and mononuclear.

17.2.3.2.1.7

### Ovine fleece rot

Ovine fleece rot is a superficial bacterial dermatitis usually caused by excessive moisture (usually in the form of rain) that penetrates the fleece (wool), wets the skin, and causes proliferation of *Pseudomonas* spp. Approximately 1 week of continual wetting is usually sufficient to cause marked proliferation of the bacteria on the skin and in the fleece. This is followed by an acute inflammatory response with serum exudation and matting of the fleece. The fleece is also discolored because of production of pigments (chromogens) by the pseudomonas bacteria and has a rotten odor. Microscopic lesions include epidermal pustular dermatitis and superficial folliculitis. Ovine fleece rot is important economically because the malodor attracts flies, predisposing to myiasis (infestation of tissue by the larvae of dipterous flies), and the value of the affected wool is reduced.

17.2.3.2.1.8

### Superficial bacterial folliculitis

Staphylococcal folliculitis and furunculosis are discussed with deep bacterial infections next.

17.2.3.2.2

### Deep Bacterial Infections (Deep Pyodermas)

Deep pyodermas are bacterial infections of the hair follicle, dermis, and/or subcutis. They are caused by a variety of bacteria, including *Staphylococcus* sp., *Streptococcus* sp., *Corynebacterium pseudotuberculosis*, *Pasteurella* sp., *Proteus* sp., *Pseudomonas* sp., and *Escherichia coli*. *Staphylococcus intermedius* is the primary pathogen of canine skin. Organisms typically enter the skin via natural pores such as hair follicles or any form of wound, including direct penetration of the skin. Deep bacterial infections of hair follicles often have predisposing causes, such as immune suppression, demodicosis (dogs), or disorders associated with follicular hyperkeratosis (callus or comedo formation), and also originate as a sequela to superficial bacterial folliculitis. Deep bacterial infections are less common than superficial infections and develop most frequently in dogs.

17.2.3.2.2.1

### Staphylococcal folliculitis and furunculosis ([Table 17-9](#))

Infection of the hair follicle can be superficial or deep. Superficial infections involve the follicular infundibulum but can spread to involve the deeper portions of the follicle (the infundibulum and below). Mild to moderate folliculitis without furunculosis can resolve completely with appropriate antibiotic therapy. However, untreated or severe folliculitis can progress to involve deeper aspects of the follicle and result in follicular distention with rupture (furunculosis) and release of follicular contents (hair, follicular stratum corneum, bacteria) into the dermis and sometimes subcutis. The bacteria proliferate in the deep dermis and subcutis and can reach draining lymph nodes. Draining tracts often develop as a foreign body response to extruded follicular contents (e.g., hair and follicular stratum corneum). Thus the infection and severe inflammation spread into the surrounding dermis and subcutis, resulting in the need for intensive long-term treatment and increasing the potential for systemic infection and local scarring.

Staphylococcal folliculitis and furunculosis develop most commonly in the dog ([Figs. 17-28 and 17-29](#)), frequently affect the horse, goat, sheep, but are uncommon in the cow, cat, and pig. In dogs, lesions are localized or generalized and develop on the dorsal nose, pressure points, interdigital areas, and chin. Other cutaneous areas can also be affected, especially if predisposing conditions (e.g., follicular dysplasia, cornification disorders, or demodicosis) are present. Deep pyoderma of adult German shepherd dogs (German shepherd folliculitis, furunculosis, and cellulitis) is a unique deep pyoderma with an apparent genetic predisposition. Lesions are located on the dorsal lumbosacral, ventral abdominal, and thigh areas. Hypersensitivity to the bites of fleas or alterations in immune or neutrophil function have been proposed as predisposing causes, but most of these potential causes have been discounted. Deep folliculitis and furunculosis, especially on the cheek area or neck of some large-breed dogs (golden and Labrador retriever, Saint Bernard, and Newfoundland), can clinically resemble superficial pyotraumatic dermatitis (acute moist dermatitis), belying the deep nature of the lesions.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Table 17-9 Bacterial Folliculitis and Furunculosis
--

Organisms	Predisposing Causes	Portal of Entry	Clinical Lesions	Histologic Lesions	Anatomic Locations	Species
-----------	---------------------	-----------------	------------------	--------------------	--------------------	---------

## Pathologic Basis of Veterinary Disease, 4th Edition

<i>Staphylococcus</i> sp. are most frequently involved	Superficial folliculitis: Allergy	Hair follicle openings	Superficial folliculitis: Papules, crusted	Superficial: Superficial luminal folliculitis	Dorsal nose, pressure points, interdigital areas, chin, and can be generalized	Dog; common
Others: <i>Streptococcus</i> sp., <i>Corynebacterium pseudotuberculosis</i> , <i>Pasteurella</i> sp., <i>Proteus</i> sp., <i>Pseudomonas</i> sp., and <i>Escherichia coli</i> factors	Seborrhea		papules, pustules, epidermal collarettes, and alopecia	Deep: Superficial and deep suppurative luminal folliculitis with follicular distention often in conjunction with furunculosis	Goat; frequent	Horse; frequent
	Local irritants		Deep folliculitis: Same as superficial folliculitis plus hemorrhagic bullae, nodules, and draining tracts	Pyogranulomatous dermatitis in response to release of follicular contents	Area covered by tack, especially the skin of the saddle area, the tail, or on the caudal aspect of the pastern <sup>*</sup> or fetlock <sup>†</sup>	Cattle, more in young bulls; uncommon
	Matted hair coats			Tracts that drain to the surface	Face, pinnae, distal limbs, and glabrous areas of the udder, ventral abdomen, medial thighs, and perineum	Piglets; uncommon
	Deep folliculitis:			Scarring with loss of adnexa and permanent alopecia localized to affected skin		Cat; rare
	Sequel to superficial bacterial folliculitis				Adult sheep: face, especially around the eyes, ears, base of horns, limbs, or teats	
	Immune suppression				Lambs: mild lesions most commonly on the lips and perineum; usually	
	Stresses (large animals)				spontaneously regress	
	Demodicosis (dogs)				Tail, perineum; less often scrotum and face	
	Follicular hyperkeratosis (callus or comedones)				Piglets younger than 8 weeks: generalized body hindquarters, abdomen, chest	
	Irritation from tack (horses)				Young growing piglets: facial lesions related to sharp canine	
	Increased environmental temperature and moisture (horse)					
	Pastern folliculitis (horses):					
	Excessive moisture, trauma, contact dermatitis, mite					

## Pathologic Basis of Veterinary Disease, 4th Edition

infestation	teeth
	Crusted papular eruption indistinguishable from miliary dermatitis, anywhere, including head and neck
* Pastern (proximal interphalangeal articulation).	
† Fetlock (metacarpophalangeal articulation).	

In horses, lesions develop most commonly in association with tack, especially on the skin of the saddle area, the tail, or the caudal aspect of the pastern (proximal interphalangeal articulation) or fetlock (metacarpophalangeal articulation). When the skin of the pastern or fetlock is involved, the condition is called equine pastern folliculitis (a.k.a. grease heel, scratches). Equine pastern folliculitis is a complex disorder in which secondary staphylococcal folliculitis plays a role. Predisposing factors are numerous and include excessive moisture, trauma, and contact dermatitis. Also, many other conditions affect the pastern skin in horses, including immune-mediated diseases (pemphigus foliaceus, vasculitis, photosensitization), other infections (dermatophilosis, dermatophytosis), and mite infestation (*Chorioptes* sp.), necessitating an early thorough clinical evaluation and sometimes microbiologic or histopathologic evaluation to differentiate staphylococcal folliculitis of the skin of the pastern from these other disease processes. In severe chronic lesions, initiating causes may no longer be identifiable.

In goats, the face, pinnae, distal limbs, and glabrous areas of the udder, ventral abdomen, medial thighs, and perineum are most commonly affected. In adult sheep, lesions develop on the face, especially around the eyes, or on the limbs or teats. In otherwise healthy lambs, mild lesions develop most commonly on the lips and perineum, and usually spontaneously regress.

Grossly the lesions of superficial folliculitis include papules, crusted papules, pustules, epidermal collarettes, and alopecia. Deep folliculitis can have similar lesions plus hemorrhagic bullae, nodules, and draining tracts. The microscopic patterns include superficial or deep luminal folliculitis, pyogranulomatous furunculosis, draining sinuses, and occasionally, panniculitis. Microscopic lesions include suppurative luminal folliculitis with follicular distention often in conjunction with furunculosis. Pyogranulomatous dermatitis in response to release of follicular contents is often severe, may efface the dermal architecture, extend into the deep dermis and panniculus, and form tracts that drain to the surface. Scarring can lead to loss of adnexal structures and permanent alopecia localized to affected skin.

### 17.2.3.2.2.2

#### Subcutaneous abscesses

Subcutaneous abscesses are localized collections of purulent exudate located within the dermis and subcutis. Abscesses are common in cats because of the frequency of bacterial contamination of puncture wounds. Abscesses also are common in large animals. In addition to puncture wounds, other predisposing causes include foreign bodies, injections, and shearing and clipping wounds. Granulation tissue or mature fibrous connective tissue borders the exudate. Subcutaneous abscesses frequently rupture and drain spontaneously, and heal by scarring. A wide variety of bacteria can cause subcutaneous abscesses. Commonly isolated bacteria include *Pasteurella multocida* (dog and cat bite wounds), *Corynebacterium pseudotuberculosis* (horses, sheep, and goats), and *Arcanobacterium*

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*pyogenes* (sheep, goats, cattle, pigs). Other frequently isolated bacteria include  $\beta$ -hemolytic streptococci, *Fusobacterium* sp., *Peptostreptococcus* sp., *Bacteroides* sp., *Staphylococcus* sp., and *Clostridium* sp.

17.2.3.2.3

### Bacterial Granulomatous Dermatitis (Bacterial Granulomas)

Bacterial granulomatous dermatitis is usually caused by traumatic implantation of bacteria, which are generally saprophytes of low virulence. Causative organisms usually stimulate a strong cell mediated-immune response by persisting as an antigen in the tissue. Grossly, lesions are slowly progressive, nodular or diffuse, and can ulcerate and drain through the surface of the skin via fistulas. Microscopic lesions consist of mixed populations of inflammatory cells, especially macrophages, thus lesions are granulomatous to pyogranulomatous. Multinucleated giant cells and caseous necrosis are present in some lesions. Causal agents can be present in macrophages, exudate, or in clear spaces or fat vacuoles within tissue but are often in such low numbers that they are difficult to identify in histologic sections.

17.2.3.2.3.1

### Mycobacterial granulomas

Mycobacterial organisms produce granulomatous to pyogranulomatous dermatitis and panniculitis in many species of animals, particularly cats and less frequently dogs and cattle. The majority of mycobacteria are intracellular pathogens that are able to persist in tissue by entering macrophages. Many are able to survive and replicate within the macrophages by inhibiting fusion with lysosomes. Tissue destruction results from persistence of antigen in the tissue and a cell-mediated inflammatory response. Infection occurs with obligate pathogens that require a vertebrate host to multiply and saprophytes in the environment that occasionally cause opportunistic infections. Infection occurs with the tuberculosis group considered to be obligate pathogens (*Mycobacterium tuberculosis*, *Mycobacterium bovis*), the leprosy group considered to be obligate pathogens (*Mycobacterium lepraemurium*), and the opportunistic group considered to be saprophytes or facultative pathogens (subdivided based on growth rate and pigment production). Rapid-growing opportunistic organisms (*Mycobacterium fortuitum*, *Mycobacterium smegmatis*, *Mycobacterium chelonae*, *Mycobacterium abscessus*, and *Mycobacterium thermoresistibile*) and slow-growing opportunistic organisms (*Mycobacterium avium-intracellulare* complex, *Mycobacterium kansasii*, *Mycobacterium ulcerans*) are inhabitants of soil, water, and decomposing vegetation, and infection tends to occur via wound contamination or traumatic implantation. To avoid confusion in terminology, by convention, infections caused by *Mycobacterium tuberculosis* and *Mycobacterium bovis* are referred to as “tuberculosis.” In contrast, infections caused by other mycobacterial agents are referred to as “mycobacteriosis,” which is sometimes further defined by the group of agents involved (e.g., atypical, opportunistic, or avian).

1185

1186

Mycobacterial infection is more common with the rapidly growing opportunistic mycobacteria (also called atypical mycobacteria), and infections are more common in cats, in which lesions are characterized by recurrent nodules, with draining sinuses frequently located in the dermis and subcutis of the inguinal area. The microscopic lesions are characterized by pyogranulomatous inflammation. Organisms are more often found extracellularly in clear spaces sometimes lined by neutrophils (Fig. 17-50). Infections with the slow-growing, opportunistic mycobacteria are more commonly disseminated (not limited to the skin) and resemble those caused by *Mycobacterium tuberculosis*.

Fig. 17-50 **Atypical mycobacteriosis (opportunistic mycobacterial infection), rapidly growing *Mycobacterium* sp., pyogranulomatous panniculitis, skin, abdomen, cat. A**, Note the draining sinuses (*arrows*) that overlie areas of nodular pyogranulomatous inflammation in the dermis and panniculus. **B**, Note pyogranulomatous inflammation (neutrophils and macrophages) surrounding a vacuole containing bacteria. In atypical *Mycobacterium* sp. infections of this type, the mycobacterial organisms are extracellular. H&E stain. *Inset*: Pyogranulomatous inflammation with a vacuole containing acid-fast bacilli. Fite's method for acid-fast organisms. (**A**, Courtesy Dr. David Duclos, Animal Skin and Allergy Clinic. **B** and *Inset*, Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.)

In cattle, cutaneous infections with opportunistic mycobacterial organisms, historically called “skin tuberculosis,” occur as single or multiple nodules 1 to 8 cm in diameter in the dermis and subcutis, particularly of the lower legs. But lesions can spread to the thighs, forearms, shoulder, and abdomen through skin lymphatics. The skin of the udder is sometimes involved. The lymph nodes are unaffected. The causative organisms are thought to be saprophytic atypical mycobacteria that probably enter through cutaneous abrasions. In most of these infections, the specific mycobacteria have not been identified by culture, but *Mycobacterium kansasii* has been identified in a few cases. A more appropriate name for this condition is bovine cutaneous opportunistic mycobacteriosis. Clinical lesions are either firm or fluctuant nodules connected by thin cords of tissue that represent inflamed lymphatic channels (lymphangitis). The firm nodules consist of pyogranulomatous inflammation with fibrosis and sometimes mineralization. The fluctuant nodules are thick-walled abscesses that can ulcerate, rupture, and drain thick, tan exudate. Small lesions can spontaneously resolve, but larger lesions are persistent. This disease became apparent during the time of intense tuberculosis eradication efforts because infection with these opportunistic mycobacterial organisms can cause false-positive reactions to bovine tuberculin tests. Bovine cutaneous opportunistic mycobacteriosis is much less commonly identified in current times, partly because the prevalence of and thus testing for bovine tuberculosis has been reduced.

1186

1187

Feline leprosy, caused by *Mycobacterium lepraemurium* and probably other mycobacterial organisms (see later discussion) develops in cats living in cold, wet areas of the world, including the northwestern United States and Canada. Mode of transmission is not known, but bites of cats or rodents, soil contamination of cutaneous wounds, or possible transmission via biting insect vectors may be involved. *Mycobacterium lepraemurium* does not grow in culture using standard techniques but has been identified by polymerase chain reaction (PCR) with DNA sequencing. These molecular techniques have resulted in the identification of other, potentially causative, mycobacterial agents (i.e., *Mycobacterium visibilis* [*Mycobacterium visibile*]) in cutaneous lesions clinically consistent with feline leprosy. Lesions develop most commonly on the head, neck, and limbs but can occur anywhere (Fig. 17-51). Histologically, two distinct morphologic patterns of inflammation are present. In one, there is diffuse granulomatous inflammation without necrosis and with large numbers of intracellular acid-fast bacilli. In the other pattern, there are granulomas with central necrosis surrounded by a zone of lymphocytes. Few to moderate numbers of acid-fast bacilli are generally limited to the areas of necrosis.

Rarely a nodular granulomatous dermatitis due to acid-fast bacilli develops on the head, dorsal pinnae, or other distal extremities in dogs, often with short-hair coats (canine leproid granuloma syndrome). Saprophytic mycobacterial organisms transmitted via the bites of flies are thought to be the cause of the syndrome. The dogs are healthy otherwise, and cultures are negative.

Cutaneous infections caused by *Mycobacterium tuberculosis* and *Mycobacterium bovis* are rare; alimentary and pulmonary infections are more common, but skin infections can develop alone or in combination with disseminated infection. Tentative diagnosis of mycobacterial infections is made by considering the animal species affected, clinical lesion appearance and location, and cytologic or histopathologic detection of acid-fast bacilli. In the past, culture was required for definitive identification of the organism involved. The acid-fast bacilli can be rare in tissue sections, especially with the saprophytic opportunistic agents, and some organisms, such as those in feline leprosy and canine leproid granuloma syndrome are exceedingly difficult to grow on culture media; thus diagnosis is challenging. Fortunately the need for cultural identification is being reduced by use of immunohistochemistry and PCR techniques that can identify the organisms or their genetic material in tissue and can be completed within a few days. The use of genetic techniques is enhancing studies of mycobacterial diseases in human beings and animals. For example, within the genus *Mycobacterium*, 42 new species have been detected since 1990. It is likely that taxonomy of mycobacterial diseases will be refined based on the use of the genetic techniques.

Fig. 17-51 **Feline leprosy syndrome, *Mycobacterium lepraemurium* (and sometimes other *Mycobacterium* sp.), nodular granulomatous panniculitis, subcutis, cat.** **A**, Leg. Note multiple grouped nodules (arrows) consisting of granulomatous inflammation. In feline leprosy, slowly growing nodules are present in the skin or subcutis, especially of the face, forelegs, or trunk. **B**, Macrophages contain numerous mycobacteria (arrows). ### 17.2.3.2.3.2

#### Bacterial granulomatous dermatitis caused by other bacteria

Botryomycosis is a term for a granulomatous dermatitis caused by nonfilamentous bacteria, typically *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas aeruginosa*, *Actinobacillus lignieresii*, and *Proteus* spp. In botryomycosis, these bacteria form small yellow “sulfur” granules, which consist of centrally located bacterial colonies surrounded by radiating club-shaped bodies of homogeneous eosinophilic material termed Splendore-Hoeppli material. This material is considered to be antigen-antibody complexes. Clinically the lesions are progressive nodular masses located in cutaneous or subcutaneous areas and that are composed of granulomatous inflammation with the embedded bacterial colonies bordered by the Splendore-Hoeppli material. Histologic differential diagnoses of botryomycosis include infections with filamentous bacteria that cause similar nodular masses (actinomycotic mycetomas) and nodular masses caused by fungi (eumycotic mycetomas). 1187 1188

Filamentous bacteria also cause bacterial granulomatous dermatitis with granules bordered by Splendore-Hoeppli material and are differentiated from botryomycosis by gram staining and culture. The bacteria are introduced through traumatic injury; are gram-positive, filamentous, and branching; and include various species of *Nocardia* and *Actinomyces*. Other actinomycetes (e.g., *Actinomadura*, *Streptomyces*) can also contribute. The granules contain mycelial filaments that are 1 µm or less in diameter. *Nocardia* spp. have a limited tendency to clump together; thus they typically do not form granules. The clinical lesions are progressive nodular cutaneous and subcutaneous masses, often with draining sinuses, which can extend into and involve underlying bone. These nodular masses are called “actinomycotic mycetomas.” Histologic lesions are nodular areas of granulomatous inflammation with abundant fibrosis and embedded bacterial colonies bordered by Splendore-Hoeppli material. Histologic differential diagnoses include botryomycosis and mycetomas caused by fungi (see Subcutaneous Mycoses, Eumycotic Mycetomas). A classic example of actinomycotic mycetoma in cattle is the so-called “lumpy jaw” wherein the infection begins via traumatic implantation of *Actinomyces bovis* into the mandibular mucosa (rather than skin), which progresses to involve mandibular bone (see Chapter 16).

### 17.2.3.2.4

#### Dermal Lesions Secondary to Systemic Bacterial Infections or Infection with Toxin Producing Bacteria

Systemic bacterial infections can cause skin lesions in animals by bacterial embolization to the skin during sepsis, toxin production, direct infection of vascular endothelial cells, or precipitation of immune-complex disease. In some infections, more than one mechanism is involved. Lesions often reflect vascular damage, specifically vasculitis and thrombosis.

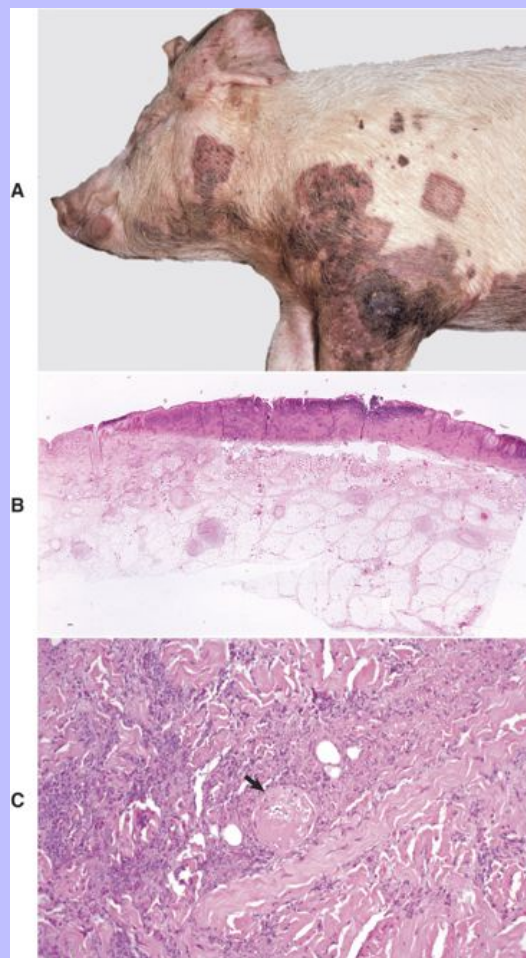

Cutaneous lesions caused by *Erysipelothrix rhusiopathiae* (erysipelas) in pigs are a result of bacterial embolization to the skin during sepsis. Lesions consist of square to rhomboidal, firm, raised, pink to dark purple areas (Fig. 17-52) and are caused by vasculitis, thrombosis, and ischemia (infarction). The rhomboidal shape likely represents the area of skin supplied by the thrombosed vessel.

Septicemic salmonellosis causes cyanosis of the external ears and abdomen because of capillary dilation, congestion, and thrombosis. The thrombosis leads to necrosis of distal extremities. The mechanism of vascular damage involves endotoxin-induced venous thrombosis. Systemic infection with *Pasteurella multocida* can cause similar lesions in pigs. *Escherichia coli* production of Shiga-like toxin-II causes edema disease of pigs. The Shiga-like toxin damages the endothelium and tunica media of small arteries 1188 1189

## Pathologic Basis of Veterinary Disease, 4th Edition

and arterioles throughout the body, causing vascular degeneration, necrosis, and edema. Gross lesions of the skin in edema disease consist of accumulation of clear fluid (edema) in the subcutis of the snout, eyelids, submandibular area, ventral abdomen, and inguinal areas. Histologically the subcutis is edematous and sometimes, edema, hemorrhage, smooth muscle necrosis, and hyaline degeneration of the tunica media of vessels may be evident in the skin and other areas of the body.

**Fig. 17-52 Erysipelas, skin, pig.** **A**, The reddish rhomboidal lesions in the skin are infarcts secondary to thrombosis, from the embolization of septic emboli. **B**, The epidermis and dermis are necrotic from infarction. The only normal dermis and epidermis are at the extreme left. H&E stain. **C**, Note the thrombosis of the vessel (arrow). H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Recently, conditions that resemble toxic shock syndrome in human beings have been described in dogs. *Streptococcus canis* has been documented as the cause in most dogs; however, other bacteria, especially *Staphylococcus intermedius*, that produce exotoxins—including toxic shock syndrome toxin-1—could potentially play a role. The site of infection can be the skin, as seen with necrotizing fasciitis (inflammation of the subcutaneous fat and fascial planes); however, the primary site of infection in some dogs has been the lung or urinary tract. Initial clinical signs in dogs with necrotizing fasciitis include rapid onset of extreme pain associated with a relatively minor wound or blunt injury to skin. The bacteria are thought to enter through a minor cutaneous wound anywhere on the body and produce exotoxins leading to severe tissue damage initially in the region of the skin injury. However, the portal of entry or initial wound in some cases of necrotizing fasciitis may not be apparent. Clinically, lesions of necrotizing fasciitis are painful, hot, and swollen. The subcutaneous fat, fascia, and overlying skin can become necrotic and can slough. The swelling is due to necrosis of fat and exudate accumulating between the fascial planes (fasciitis and/or cellulitis). Histologic lesions include edema, hemorrhage, necrosis, suppurative inflammation, and thrombosis. Occasionally, vasculitis and colonies of cocci are seen. The condition can rapidly lead to sepsis, multiorgan failure, and death if not treated early and aggressively. In dogs with toxic shock–like syndrome, but without necrotizing fasciitis, clinical skin lesions include multicentric to generalized cutaneous erythema. Some dogs also have edema and vesicles or pustules that progress to ulcers. The ears, extremities, and ventrum are frequently affected, and dogs can be depressed and have fever, anemia, thrombocytopenia, and neutrophilia. Histologically, these dogs have superficial dermatitis with apoptotic keratinocytes bordered by neutrophils. The lesions can progress to full-thickness necrosis and ulceration of the epidermis. As in necrotizing fasciitis, lesions can be fatal without early therapy with appropriate antibiotics. The cause of the skin lesions in the dogs with toxic shock–like syndrome, but without necrotizing fasciitis, has not been determined. In human beings, the pathogenesis of the skin lesion is thought to be a result of nonspecific stimulation of lymphocytes by exotoxins with superantigen activity and the release of cytokines, including TNF- $\alpha$ .

Bacterial infections can also develop from direct extension of bacterial infections of deeper tissue, such as clostridial myositis and cellulitis. *Clostridium novyi* can cause severe cellulitis, toxemia, and death in young rams whose heads have been traumatized by butting during the breeding season. Spores in the soil gain entrance through cutaneous lacerations at the base of the horns, germinate, produce toxins, and result in cellulitis and toxemia. Swelling of the head and neck result in the common term “big head” or “swelled head.” *Clostridium chauvoei* is a secondary invader of wounds, where spores can germinate, proliferate, and produce necrotizing and hemolytic exotoxins leading to extensive necrosis of the skin and underlying tissue (gas gangrene).

Rocky Mountain spotted fever, the most important rickettsial disease associated with cutaneous lesions, is caused by *Rickettsia rickettsii*, an organism that infects endothelial cells. This organism is transmitted by ticks, mainly *Dermacentor andersoni* and *Dermacentor variabilis*. The disease is seasonal, corresponding with the increased activity of ticks and contact with ticks. In addition to systemic signs, affected dogs have cutaneous, ocular, genital, and oral erythema with petechiae, edema, necrosis, and ulceration as a result of the direct endothelial cell damage and vasculitis caused by the rickettsia.

In horses, purpura that develops occasionally as a sequela to *Streptococcus equi* are caused by immune-complex vasculitis. Clinically, horses have petechial hemorrhages of the skin and mucous membranes and edema with serum exudation of distal extremities. Microscopic lesions consist of vascular wall disruption by neutrophils (neutrophilic vasculitis), perivascular edema, hemorrhage, and fibrin exudation.

17.2.3.2.5

### Digital Infections of Ruminants (Bacterial Pododermatitis)

Infections of the digits of cattle and sheep are usually mixed bacterial infections sometimes separated into two basic groups, “contagious foot rot” and “necrobacillosis of the foot,” based on the contagious nature of the infection and the type of bacteria principally responsible for infection (Table 17-10).

Contagious foot rot is caused principally by *Dichelobacter nodosus* (formerly *Bacteroides nodosus*) acting synergistically with *Fusobacterium necrophorum* and other bacteria. Necrobacillosis of the foot is caused principally by *Fusobacterium necrophorum* and other bacteria, including *Bacteroides melaninogenicus* in cattle.

1189

1190

17.2.3.2.5.1

### Contagious foot rot

Contagious foot rot in sheep develops when predisposing factors, such as moisture and trauma, damage the interdigital epidermis and allow colonization by a variety of microorganisms, including *Fusobacterium necrophorum* from skin or feces. If the sheep harbors the obligate anaerobic bacteria, *Dichelobacter nodosus* in interdigital skin, foot rot will develop. Contagious foot rot is a synergistic bacterial infection principally involving *Dichelobacter nodosus* (elaborates proteases and growth-enhancing factors, which aid bacterial penetration of the epidermis and bacterial growth) and *Fusobacterium necrophorum* (responsible for most of the necrosis and inflammation). Contagious foot rot in sheep occurs in virulent and benign forms. The virulent form is due to more virulent *Dichelobacter nodosus* that produces significantly more proteolytic enzymes (proteases including elastase), allowing more bacterial penetration of the epidermis. The proteases in the virulent form also tend to be more heat stable. Virulent foot rot is more persistent (can last for more than 1 year if not treated), affects a high percentage of sheep, affects more than one foot, and can result in death of sheep due to emaciation as a result of severe pain and reluctance to graze. Early lesions of virulent foot rot begin in the interdigital axial (inner) bulbar notch, affect both digits, and consist of red, moist, and swollen eroded skin. The infection spreads around the bulb of the heel to the epidermal matrix of the hoof and results in a malodorous exudate that separates the horn from the interdigital skin. Lesions progress to the bulb and sole, and finally to the axial and abaxial (outer) surfaces of the hoof wall. The germinal epithelium is not destroyed and regeneration is attempted, but the new horn is destroyed. In chronic infections, hooves can become long and misshapen. Benign foot rot (foot scald) is mild, confined to interdigital skin, and can have slight separation of the horn of the heel; also the hoof can overgrow. Foot rot in cattle is similar to benign foot rot in sheep.

1190

1191

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-10 Digital Infections of Ruminants

Species	Disorder	Predisposing Factors	Bacteria Involved	Severity	Contagious
Sheep	Contagious foot rot, virulent form	Moisture and trauma	<i>Dichelobacter nodosus</i> plus <i>Fusobacterium necrophorum</i> and other bacteria	Severe; virulent strains of <i>Dichelobacter nodosus</i> produce more proteolytic enzymes	Yes
Sheep	Contagious foot rot, benign form (foot scald)	Moisture and trauma	<i>Dichelobacter nodosus</i> <i>Fusobacterium necrophorum</i>	Mild; less virulent strains of <i>Dichelobacter nodosus</i> produce fewer proteolytic enzymes and are less pathogenic	Yes
Sheep	Necrobacillosis of the foot I. Ovine interdigital dermatitis		<i>Fusobacterium necrophorum</i> Other bacteria, but no <i>Dichelobacter nodosus</i>	Clinically similar to benign foot rot	No
	II. Foot abscesses	Wet seasons	<i>Fusobacterium necrophorum</i>	Can cause severe lameness with permanent foot deformity	No
	A. Heel abscesses (infective bulbar necrosis) B. Toe abscesses (lamellar abscesses)	Heavy adult sheep	<i>Arcanobacterium pyogenes</i>		
Cattle	Foot rot	Trauma and moisture	<i>Dichelobacter nodosus</i> <i>Fusobacterium necrophorum</i> Other bacteria	Mild; similar to benign foot rot in sheep	Yes
Cattle	Necrobacillosis of the foot (foul-in the-foot)	Trauma	<i>Fusobacterium necrophorum</i> <i>Bacteroides melaninogenicus</i>	Can be severe with cellulitis involving tendons, joints, and bone	No
Cattle	Papillomatous digital dermatitis (foot warts; hairy heel warts)	Prolonged wet conditions	Probably <i>Treponema</i> sp. spirochete	Moderate to severe lameness	Yes

17.2.3.2.5.2

### Necrobacillosis

Necrobacillosis of the foot in sheep includes ovine interdigital dermatitis and foot abscesses. Ovine interdigital dermatitis is an acute necrotizing dermatitis that clinically is similar to benign foot rot. Ovine interdigital dermatitis is differentiated from foot rot by the failure to demonstrate *Dichelobacter nodosus* in smears or cultures of exudate. Foot abscesses include heel abscesses (infective bulbar necrosis) and toe abscesses (lamellar abscesses). Foot abscesses are more common in wet seasons and

## Pathologic Basis of Veterinary Disease, 4th Edition

in heavy adult sheep. In addition to *Fusobacterium necrophorum*, *Arcanobacterium pyogenes* (*Actinomyces pyogenes*) may be isolated from the lesions.

Necrobacillosis (foul-in-the-foot) of cattle occurs secondary to trauma to the interdigital skin and is caused by *Fusobacterium necrophorum* and *Bacteroides melaninogenicus*. There is lameness with an interdigital dermatitis and cellulitis with fissures and necrosis that may extend into the deeper structures of the foot, such as the distal phalanx, distal sesamoid bone, distal interphalangeal joint, and tendons.

17.2.3.2.5.3

### Papillomatous digital dermatitis

Papillomatous digital dermatitis, also known as foot warts or hairy heel warts, is a painful, contagious dermatitis of the feet of cattle (Table 17-10). It occurs worldwide. The cause of papillomatous digital dermatitis is unknown, but spirochetes belonging to the genus *Treponema*, structurally similar to *Borrelia burgdorferi*, are suspected. The condition is also usually associated with management conditions in which the feet of cattle remain wet for prolonged periods. The pathogenesis of lesion formation is not yet known. Papillomatous digital dermatitis most commonly affects the skin proximal and adjacent to the interdigital space at the caudal (plantar) aspect of the hind feet. Early gross lesions are well-circumscribed, round-to-oval, red plaques up to 6 cm in diameter with a moist granular surface prone to bleeding and with a very strong, pungent odor. Lesions are partially to completely alopecic and can be bordered by hypertrophied hairs two to three times longer than normal. Microscopically, this corresponds to areas of mild epidermal hyperplasia with foci of erosion, necrosis, ballooning degeneration, and microabscesses. The dermis contains minimal perivascular inflammation. Mixed bacteria can be present in the outer necrotic debris, but only spirochetes are present in the deeper viable epidermis. The lesions become progressively more proliferative and less painful with time. Mature lesions are irregular wartlike growths or filamentous papillae that measure 0.5 to 1.0 mm in diameter and 1 mm to 3 cm in length and are pale yellow, gray, or brown. Histologically the older lesions are composed of frondlike projections or plaques of markedly hyperplastic epidermis with parakeratosis and hyperkeratosis. Foci of necrosis and hemorrhage, ballooning degeneration, and aggregates of neutrophils are scattered throughout the hyperplastic epidermis (Fig. 17-53). At this later stage, inflammation is more intense in the dermis and plasma cells can be numerous. Lesions are painful, forcing the animal to shift its weight to the toe of the affected foot, which results in a smooth contour to the toe (clubbing) and atrophy of the bulbs of the heels.

Papillomatous digital dermatitis is economically important because it frequently causes moderate to severe lameness that results in weight loss, decreased milk production, and poor reproductive performance. The vast majority of cases are in dairy cows, but the infection has also been reported in beef cattle. Although the disease occurs in cattle of all ages, the highest incidence appears to be in replacement dairy heifers.

17.2.3.3

### FUNGAL (MYCOTIC) INFECTIONS

Mycotic infections have been classified into four basic categories: superficial, cutaneous, subcutaneous, and systemic (Box 17-9). Ability to mount an inflammatory response is paramount to clearing the infection. Mycotic infections tend to occur more often in animals with compromised resistance because of debilitating systemic diseases—such as diabetes mellitus or neoplasia—or in animals treated with glucocorticoids or other immunosuppressive agents or with long-term, broad-spectrum antibiotics.

### 17.2.3.3.1 Superficial Mycoses

Superficial mycoses are infections restricted to the stratum corneum or hair with minimal or no dermal reaction. Piedra is a rare superficial mycosis caused by *Trichosporon beigelii* and has been reported in horses and dogs. Lesions consist of minute swellings restricted to the extrafollicular portion of the hair shaft.

### 17.2.3.3.2 Cutaneous Mycoses

Cutaneous mycoses (also included as superficial mycoses by some authors) are infections of keratinized tissue, including hair, claws, and epidermis. The fungi are usually restricted to the cornified layers and only very rarely are found in the dermis or subcutis, but tissue destruction and host response can be extensive. Infections in animals include dermatophytosis, cutaneous candidiasis, and *Malassezia* dermatitis.

1191

1192

Fig. 17-53 **Papillomatous digital dermatitis, skin, cow.** **A**, Note the moist, irregular, and reddened alopecic areas on the bulbs of the heel. The lesions are of several weeks to a few months duration. **B**, Note the papillated epidermal hyperplasia (see also [Fig. 17-12](#)). The epidermis is thickened by hyperkeratosis and acanthosis. Most of the acanthotic cells have ballooning degeneration. The hyperplastic epidermis covers dermal papillae, which contain hyperemic vessels and foci of mixed inflammatory cells. H&E stain. 17.2.3.3.2.1

### Dermatophytoses

Dermatophytoses are fungal infections of the skin, hair, and claws of animals caused by taxonomically related fungi known as dermatophytes. Pathogenic genera include *Epidermophyton*, *Microsporum*, and *Trichophyton*. Dermatophytosis occurs worldwide, is the most important cutaneous (superficial) mycosis, and is common in human beings and animals, especially cats. Superficial and cutaneous mycoses (dermatophytosis) are acquired by contact with infected animals or by contact with scales shed from infected animals. Dermatophytes are able to colonize the cornified structures (hair, claws) and the stratum corneum and cause disease without ever entering living tissue. Clinical disease in a dermatophyte infection is the result of the host's reaction to the organism and its by-products. Dermatophytes are more contagious than other fungal infections, are more common in hot, humid environments, and young animals are more susceptible than adults. Animals kept in overcrowded, dirty, or damp areas and those with inadequate nutrition are also more susceptible. Species that more commonly infect domestic animals are included in the genera *Microsporum* and *Trichophyton*. *Epidermophyton* is adapted to human beings (anthropophilic) and rarely infects animals. Zoophilic dermatophytes (e.g., *Microsporum canis*) are primary animal pathogens but can infect human beings. *Microsporum canis* is so well adapted, especially in long-haired, purebred cats that inapparent infections occur. Geophilic dermatophytes (e.g., *Microsporum gypseum*) occur in soil as saprophytes, but under favorable conditions can infect human beings and animals if the integrity of the skin is broken or the host immune system is compromised.

Cryptococcosis

Histoplasmosis

Dermatophytes invade cornified tissues (stratum corneum, hair shafts, and claws) by producing proteolytic enzymes, which help them penetrate the surface lipid coat. The fungal hyphae invade the cornified tissue, and the hyphae break into chains of arthrospores. The products elaborated by the dermatophytes cause dermal irritation and damage to the epidermis. The fungal products and cytokines released from damaged keratinocytes result in epidermal hyperplasia (hyperkeratosis, parakeratosis, acanthosis) and dermal inflammation. Inflammatory cells arrive via the superficial vessels (superficial perivascular dermatitis) and, subsequently, migrate through the epidermal layers

## Pathologic Basis of Veterinary Disease, 4th Edition

(exocytosis) to the invaded keratinized layers, forming intracorneal microabscesses. Exocytosis of inflammatory cells into follicular walls and lumens results in mural and luminal folliculitis and, if the follicular wall is destroyed, in furunculosis. Bacterial infection increases the severity of the folliculitis and furunculosis. Gross and microscopic lesions are highly variable and range from an asymptomatic infection to an eruptive nodular mass (kerion), to deep granulomatous nodular dermal and pannicular masses containing distorted fungal hyphae (pseudomycetoma), to discolored, malformed, friable, broken, or sloughed claws (onychomycosis).

**Fig. 17-54 Dermatophytosis, luminal folliculitis, skin, haired. A,** Dermatophytosis, presumed to be *Trichophyton verrucosum*, cow. Note irregularly ovoid, hairless areas with mild surface crusting. **B,** Dermatophyte infection presumed to be *Microsporum canis* involving hair follicle, dog. Note spores (arrow) along periphery and hyphae (arrowhead) within hair shaft. The hair loss is due to breakage of hair shafts and mural and luminal folliculitis, which interfere with production of new hairs and cause increased loss of old hairs. Gomori's methenamine silver nitrate–H&E counter stain. (**A**, Courtesy Dr. H. Denny Liggitt, University of Washington. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Gross lesions in haired skin are often circular or irregularly shaped, scaly to crusty patches of alopecia (Fig. 17-54), which can coalesce to involve large portions of the body. Fungi tend to die in areas of inflammation in the center of lesions but are viable at the periphery, thus giving rise to the peripheral red ring and the term “ringworm.” Hair loss is due to breakage of hair shafts and loss of hair shafts from inflamed follicles. Follicular papules and pustules can be present. In animals with severe furunculosis, the inflammation can extend into the deep dermis and subcutis leading to draining tracts. Microscopic patterns include perifolliculitis, luminal folliculitis, or furunculosis, and epidermal hyperplasia with intracorneal microabscesses. In many lesions, septate hyphae or spores are present in hair shafts and in the stratum corneum of the epidermis or follicles (Fig. 17-54, B).

1193

1194

## Pathologic Basis of Veterinary Disease, 4th Edition

17.2.3.3.2.2

### Candidiasis

Candidiasis is a yeast infection caused by *Candida* sp., normal inhabitants of the skin and gastrointestinal tract. Infection occurs when host resistance is compromised. Infections with *Candida* sp. are rare in domestic animals and usually occur on mucous membranes and at mucocutaneous junctions. Gross lesions consist of exudative and pustular to ulcerative inflammation of the lips (cheilitis), oral mucosa (stomatitis), and external ear canal (otitis externa). Microscopic lesions consist of spongiotic neutrophilic pustular inflammation, parakeratosis, and ulceration with exudation. The yeast organisms are present in the superficial exudates.

17.2.3.3.2.3

### *Malassezia* dermatitis

*Malassezia* dermatitis is caused by *Malassezia pachydermatis* (*Pityrosporum canis*), a yeast isolated from the normal external ear canal and skin. This yeast proliferates and causes clinical disease when the microclimate or host defenses are altered. Lesions can be regional (interdigital, otic, perianal, or intertriginous) or more generalized (Fig. 17-55). Grossly the lesions are erythematous, often hyperpigmented, lichenified, alopecic, and scaly. Microscopic lesions consist of hyperkeratosis, focal parakeratosis, variable spongiotic pustular dermatitis, acanthosis, and the presence of *Malassezia pachydermatis* within the surface keratin. Because *Malassezia* organisms can be lost during tissue processing, cytology is often a more reliable method of assessing the number of yeast present. Low numbers in histologic sections with lesions compatible with *Malassezia* dermatitis are often considered significant, especially with concurrent characteristic gross lesions. (Fig. 17-55).

**Fig. 17-55 Interdigital dermatitis (*Malassezia pachydermatis*), skin, dog. A**, In this dog with atopic dermatitis, the interdigital skin is erythematous, moist, and mildly lichenified indicating chronicity. **B**, Haired skin. Stratum corneum contains numerous *Malassezia pachydermatis* yeast (arrows), which are bilobed (“peanut”-shaped). The dermis is mildly edematous—note the mild separation of the collagen bundles by nonstaining to lightly amphophilic edema fluid. Gomori's methenamine silver stain–H&E counter stain. ### 17.2.3.3.3 Subcutaneous Mycoses

Subcutaneous mycoses are caused by fungi that, after traumatic implantation, invade cutaneous and subcutaneous tissue. Some infections remain localized, but others spread to the lymph vessels. Diseases in this category include eumycotic mycetomas, dermatophyte pseudomycetoma, subcutaneous phaeohyphomycosis, subcutaneous hyalohyphomycosis, sporotrichosis, subcutaneous entomophthoromycosis, and oomycosis (pythiosis and lagenidiosis, not true fungi). The gross appearance of subcutaneous mycoses and deep granulomatous infections caused by bacteria are similar, usually one or more ulcerative nodules, sometimes with draining sinuses. Microscopically the lesions of subcutaneous mycoses consist of nodular to coalescing, suppurative, pyogranulomatous, or granulomatous inflammation.

#### 17.2.3.3.3.1 Eumycotic mycetomas

Eumycotic mycetomas develop most often in horses and dogs and are rare fungal infections resulting in progressive cutaneous and subcutaneous nodular enlargements of granulomatous inflammation that can have draining sinuses and that resemble botryomycosis and actinomycotic mycetomas. The portal of entry is through traumatic injury into the dermis or subcutis, and most of the fungi involved in these infections are saprophytes. *Curvularia geniculata* is the most commonly isolated fungus in animals; other fungal genera include *Madurella*, *Acremonium*, *Pseudoallescheria*, and *Phaeococcus*. Histologic lesions are nodular masses of granulomatous inflammation with fibrosis and exudate in which there are embedded granules composed of masses of septate, branching fungal hyphae measuring 2 to 4 microns in diameter. The granules vary in size, shape, color, and texture, and are bordered by Splendore-Hoeppli material. Culture identifies the organism involved.

1194

1195

#### 17.2.3.3.3.2 Dermatophytic pseudomycetoma

Dermatophytic pseudomycetoma is a rare, deep dermal and subcutaneous infection usually caused by *Microsporum canis*, and that develops predominantly in Persian cats, suggesting the possibility of a specific genetic deficit in innate or adaptive immunity in this breed. It is presumed that follicles rupture, releasing dermatophytes into the subfollicular dermis. Gross lesions are similar to other subcutaneous mycoses. Microscopic lesions are in the subfollicular dermis or subcutis, and consist of a granulomatous inflammatory response and intermixed aggregates of fungal hyphae with irregular dilations. Hair shafts within adjacent follicles contain *Microsporum* hyphae and spores.

#### 17.2.3.3.3.3 Phaeohyphomycosis

Phaeohyphomycosis is a mycotic infection caused by species of pigmented fungi (dematiaceous) of a variety of genera that have dark-walled, septate hyphae. Genera include *Alternaria*, *Drechslera*, *Exophiala*, *Phialophora*, and others. These fungi are plant pathogens, soil saprophytes or, in some instances, normal flora that enter the skin at sites of trauma. Most of these infections remain localized to the skin and subcutaneous tissue, but they can spread to other tissue via lymphatic drainage in immunocompromised hosts. Grossly, lesions consist of alopecic or haired cutaneous nodules that can ulcerate and drain (Fig. 17-56). Microscopically, lesions consist of foci of granulomatous, pyogranulomatous, or lymphocyte-rich granulomatous inflammation containing pigmented fungal organisms. Culture is necessary for specific identification of the fungus involved. Subcutaneous

## Pathologic Basis of Veterinary Disease, 4th Edition

phaeohyphomycosis occurs in cats, cattle, horses, and rarely dogs. Hyalohyphomycosis (paecilomycosis) is similar to phaeohyphomycosis except that the fungal hyphae in tissue are nonpigmented (nondematiaceous). Organisms include *Pseudoallescheria* sp., *Acremonium* sp., *Fusarium* sp., *Paecilomyces* sp., and *Geotrichum* sp.

**A**, Infection of nasal planum and dorsum of muzzle. There is nodular ulcerative and granulomatous dermatitis primarily on the planum nasale. An ulcer is on the dorsum of the muzzle.  
**B**, Granulomatous dermatitis. Note macrophages containing yeastlike pigmented (dematiaceous) fungi (*arrows*). The presence of the pigmented fungi indicate that the condition is phaeohyphomycosis. The specific fungal organism was not cultured. H&E stain. (**A**, Courtesy Dr. Alexander Werner, Valley Veterinary Specialty Service. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.2.3.3.4

### Sporotrichosis

Sporotrichosis, caused by *Sporothrix schenckii*, is an uncommon mycosis that occurs in cutaneous, cutaneolymphatic, and disseminated forms in horses, mules, cattle, cats, and dogs. *Sporothrix schenckii* is a saprophytic dimorphic fungus found in moist organic debris, and entry into the body is by traumatic implantation. Ulcerated cutaneous nodules and fistulas develop at the site of inoculation and along lymph vessels (lymphangitis), but visceral dissemination is uncommon. Deep dermal to subcutaneous pyogranulomatous inflammation develops. Organisms are ovoid to elongate (cigar-shaped) bodies, which are often sparsely distributed and difficult to find except in cats, where organisms are numerous. The exudate containing organisms is infectious to human beings if introduced into cutaneous wounds.

1195

1196

17.2.3.3.5

### Oomycosis (pythiosis and lagenidiosis)

*Oomycosis* refers to dermal and subcutaneous infection by *Pythium insidiosum* or *Lagenidium* sp., which are both aquatic dimorphic water molds and members of the Oomycetes in the kingdom Protista. Pythiosis most often affects the skin of the limbs and trunk of dogs, cattle, cats, and horses.

## Pathologic Basis of Veterinary Disease, 4th Edition

Lagenidiosis has only been reported in dogs. Many infections develop in conjunction with exposure to freestanding water. Contamination of minor skin wounds is thought to be necessary for infection to occur. Infections are more common in tropical or subtropical climates, including the Gulf Coast of the United States, and are characterized clinically by erythematous, sometimes necrotizing, nodular lesions that ulcerate and drain (Fig. 17-57). There can be extensive tissue destruction by inflammation and necrosis. A unique gross feature of pythiosis is yellow, friable, fragments of necrotic tissue and hyphae, which can be dislodged from the lesions. Pythiosis in the dog is a rapidly progressive, debilitating, and often fatal disease seen most often in young, large-breed dogs. Lagenidiosis in the dog is also a very aggressive disease, and dogs may have lesions in organs other than the skin and lymph nodes. Histologically, hyphae or hyphal-like structures are in areas of eosinophilic to pyogranulomatous dermal or subcutaneous inflammation. Organisms may not be readily visible in H&E stained sections; thus special stains, such as Gomori's methenamine silver stain, may be required to identify the organisms. Pythiosis, lagenidiosis, and entomophthoromycosis (see next discussion) cannot be reliably differentiated from one another via examination of histologic sections. PCR assays to detect oomycotic DNA and immunoblot analyses are required to differentiate these diseases from one another. Special collection and culture techniques are also necessary.

**Fig. 17-57 Cutaneous pythiosis, *Pythium insidiosum* skin, horse. A,** Distal leg. Note the extensive ulcer with multinodular coalescing granulomatous and exudative dermatitis. Infection with *Pythium insidiosum* results in extensive inflammation and tissue damage. Necrotic tissue and inflammatory debris exude from the ulcerated surface. **B,** Note margin of necrotic debris (above) and granulomatous and eosinophilic dermatitis. Hyphal-like structures of *Pythium insidiosum* do not stain well with H&E but may be visible as irregular clear hyphal-like spaces embedded within the necrotic debris (arrows). H&E stain. **Inset:** Numerous *Pythium insidiosum* organisms stained black (arrows). Gomori's methenamine silver stain. (A, Courtesy University of Florida Clinical Dermatology Service. B and Inset, Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.)

## Pathologic Basis of Veterinary Disease, 4th Edition

17.2.3.3.3.6

### Entomophthoromycosis (zygomycosis)

*Entomophthoromycosis* refers to dermal and subcutaneous infections caused by *Basidiobolus* sp. and *Conidiobolus* sp., saprophytic fungi that gain entry to the body by inhalation or traumatic implantation by wounds or insects. Most *Basidiobolus* sp. infections have been seen in the horse. Infections with *Conidiobolus* sp. have been seen in dogs, llamas, sheep, and horses. Systemic dissemination of *Conidiobolus* sp. has developed in the dog and sheep. As in oomycosis, infections are more common in tropical or subtropical climates. Clinical and histologic features are similar to those of oomycosis. Differentiation between entomophthoromycosis and oomycosis requires culture and other techniques, such as PCR assays and immunoblot analyses, and is therapeutically important because infections with Zygomycetes (true fungi) can be responsive to antifungal treatment, whereas infections with Oomycetes are not.

1196

1197

17.2.3.3.4

### Systemic Mycoses

The respiratory tract, especially the lung, is almost invariably the primary portal of entry and infection in the systemic mycoses, but cutaneous and subcutaneous infections can occur as part of the disseminated disease or by direct implantation of fungi by trauma. Systemic mycoses include *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, and *Histoplasma capsulatum*. Infections with these fungi can occur in animals with apparently normal immune function, but are more extensive in immunocompromised animals. Grossly, one or more nodular areas in the skin can ulcerate and have draining sinuses. Histopathologically, there are nodular areas of granulomatous or pyogranulomatous inflammation in the dermis and possibly subcutis. *Cryptococcus neoformans* can cause a granulomatous response, but generally the inflammation is less severe than with the other fungi. The cryptococcal organisms have a mucinous capsule that does not stain with H&E. When inflammation is mild, the capsules of the numerous organisms in a lesion give the tissues a multicystic appearance microscopically. Cytology or microscopy is required for diagnosis. The morphologic features of the organisms (including mucicarmine-positive capsule) are sufficient for diagnosis.

17.2.3.4

### ALGAL INFECTIONS

Protothecosis is a rare infection of animals caused by achloric (colorless) alga of the genus *Prototheca*. *Prototheca* inhabit sewage, animal waste, and slime flux of trees. They enter the body via ingestion of contaminated water or food (see [Chapter 7](#)) or traumatic implantation. The organisms are usually of low pathogenicity, but severe or even disseminated infections occur in immunologically compromised hosts. Cell-mediated immunity is considered vital to control or eliminate the infection. Infection is most often reported in the dog and cat. Grossly the lesions are nodular, and the microscopic pattern is nodular to diffuse granulomatous dermatitis and panniculitis. The organisms can be identified in tissues by the characteristic endospores especially when stained with Gomori's methenamine silver stain or with immunohistochemical techniques. *Prototheca* sp. can also be identified by culture.

17.2.3.5

### PARASITIC INFECTIONS

Ectoparasites include mites and ticks (which have eight legs), and lice, fleas, and flies (which have six legs) ([Box 17-10](#)). The presence of these ectoparasites is called an infestation. Endoparasites causing cutaneous lesions include nematodes, trematodes, and protozoa, and their presence is called an infection. Parasites

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cause a number of untoward effects including damage to hides and predisposition to secondary infection. Arthropod parasites (jointed limbs) also serve as vectors of bacterial, spirochetal, helminthic, rickettsial, protozoal, and viral infections. The cutaneous reaction to parasites varies with parasite number, location, feeding habits, and host immune response. The cutaneous reaction is often mediated in part by immune mechanisms (hypersensitivity).

### 17.2.3.5.2 Mites

Mite infestations can cause serious cutaneous lesions in domestic animals and economic loss in food animals. Sheep in the United States are free of mite infestation except for *Demodex* sp'. Cattle, however, can be infested with a variety of mites, including *Sarcoptes*, *Psoroptes*, and *Chorioptes* genera, which are reportable diseases. Mite infestations are rare in horses, except for *Chorioptes* sp., which produce dermatitis of distal limbs in heavy breeds. Mite infestations can also cause serious cutaneous diseases in dogs (*Demodex canis*, *Sarcoptes scabiei*, *Otodectes cynotis*), cats (*Demodex cati*, *Demodex gatoi*, *Otodectes cynotis*, *Notoedres cati*), and pigs (*Sarcoptes scabiei*). In *Sarcoptes scabiei* infestation, mites can be difficult to find, except for infestation of the skin of the external ears of pigs.

Most species of *Demodex* mites live their entire life cycle in the lumens of hair follicles or sebaceous glands as part of the normal fauna of the skin of most mammals. It is only when the normal equilibrium between the host and the parasite is changed to favor proliferation of the mite that skin lesions of demodectic mange are produced. Thus identification of large numbers of adult mites or an increased number of immature mites in skin scrapings or biopsy samples is required for diagnosis of demodicosis. Demodicosis is caused by host-specific mites; it is a major problem in dogs, but is uncommon in other animals.

### 17.2.3.5.2.1 Demodicosis

Demodicosis is one of the most common skin disorders of dogs in North America. Canine demodicosis is caused by *Demodex canis* and occurs in two clinical forms, localized and generalized, both of which are more common in juvenile dogs. Transmission from mother to offspring occurs via

## Pathologic Basis of Veterinary Disease, 4th Edition

---

close skin contact as occurs during suckling. Purebred dogs of many breeds are predisposed to infestation, suggesting an inherited basis for the disease related to a primary deficit in cell-mediated immunity. Research studies suggest the defect is one of T-lymphocyte helper dysfunction resulting in damage by cytotoxic T lymphocytes. Active lesions of demodicosis result in lymphocytic mural folliculitis with lymphocyte-mediated damage to the keratinocytes of the follicular wall. It is speculated that follicular keratinocytes express altered self-antigens or *Demodex* antigens, which leads to immune-mediated destruction of the follicular wall. Secondary immunodeficiency, due to T-lymphocyte suppression, is also associated with demodicosis, particularly if a secondary *Staphylococcus intermedius* infection is present. The secondary immunodeficiency improves as the demodicosis resolves. Results of studies conflict as to whether the secondary immunodeficiency is caused by the accompanying bacterial infection or to the mite infestation. Demodicosis occurs in adult dogs with underlying metabolic disorders (hypothyroidism, hyperadrenocorticism) or that are given drugs (glucocorticoids or cytotoxic drugs) that can compromise the immune system. Idiopathic cases also occur.

Gross lesions of localized demodicosis in the dog consist of one to several small scaly, erythematous, alopecic, areas on the face or forelegs (Fig. 17-27). Canine generalized demodicosis usually involves large areas of the body; lesions consist of larger coalescing patches of erythema, alopecia, comedones, scales, and crusts. The early microscopic lesions include epidermal hyperkeratosis, perifolliculitis, and lymphocytic interface mural folliculitis, including mild degeneration of follicular basal cells, follicular pigmentary incontinence, and intraluminal mites (Fig. 17-27). Follicles can become plugged with large numbers of mites, keratin, and sebum. Secondary bacterial infection leads to neutrophilic folliculitis that in conjunction with mite proliferation and follicular hyperkeratosis, progresses to follicular rupture. Mites, bacteria, keratin, and sebum spill into the dermis, stimulating a granulomatous to pyogranulomatous dermatitis. Perifollicular granulomas with portions of mites are often seen. Gross lesions in dogs with severe secondary bacterial infection include papules, pustules, edema, and draining tracts. In severe demodicosis, inflammation and organisms spread into the subcutis, and lymphadenitis and septicemia can develop. Severe chronic lesions consist of dermal fibrosis with effacement of adnexal structures.

In cats, demodicosis is rare and is caused by two species of mites, one (*Demodex cati*) lives in follicles and sebaceous glands, and the other (*Demodex gatoï*) resides on the skin surface within the stratum corneum. Unless the immune response is compromised, lesions associated with *Demodex cati* are usually localized to the chin, eyelids, head, or neck. When the immune response is compromised, as in feline retroviral infections, generalized lesions of erythema, scaling, alopecia, pustules, and crusts develop. Histologically, cats with *Demodex cati* have epidermal and follicular hyperkeratosis and follicular atrophy. Inflammation is minimal. The most common sign associated with the presence of *Demodex gatoï* is pruritus, resulting in excessive grooming and symmetric alopecia. *Demodex gatoï* is contagious between cats, and there is an asymptomatic carrier state.

Demodicosis in cattle (*Demodex bovis*, *Demodex tauri*, and *Demodex ghanaensis*) and goats (*Demodex caprae*) is of little clinical significance, but extensive infection can damage hides by development of multifocal nodules in the skin of shoulders, neck, and face, or in a more generalized distribution. Nodules correspond to follicular cysts that are filled with mites and keratinaceous material. Rupture of the cysts leads to severe granulomatous dermatitis and damage to the hide. Similarly, *Demodex phylloides* of pigs causes scale-covered papules progressing to nodules that are filled with keratinaceous debris and mites, and that damage the hide. Lesions develop in the ventral body skin, eyelids, and snout. Sheep have two species of mites. *Demodex ovis* is located in hair follicles or sebaceous glands distributed over the body and can cause alopecia, erythema, scaling,

1198

1199

## Pathologic Basis of Veterinary Disease, 4th Edition

pustules, and matted fleece. Lesions develop on the face, neck, shoulders, and back, but the ears, limbs, and coronary bands can also be affected. *Demodex aries* is located in sebaceous glands of the vulva, prepuce, and nostrils, and can cause papular, rarely pustular, or nodular lesions. Demodectic mange is rare in the horse. *Demodex caballi* is commonly present in pilosebaceous units of eyelids and nose, generally without producing lesions. In contrast, *Demodex equi* is distributed over the body. Clinical lesions are rare, but when present develop on the face, neck, shoulders, or forelimbs, and consist of localized to diffuse alopecia and scaling, or of papules, nodules, and pustules.

### 17.2.3.5.2.2

#### Scabies

Scabies is caused by *Sarcoptes scabiei*. This highly contagious mite is the most important ectoparasite of pigs, is common in dogs, and is uncommon to rare in horses, cattle, sheep, goats, and cats. The mites burrow in tunnels in the stratum corneum and cause intense pruritus due principally to hypersensitivity reactions, although irritation from secretions also plays a role. Lesions begin on the external ears, head, and neck, and can become generalized. Early gross lesions include erythematous macules, papules, crusts, and excoriations. Chronic lesions are scaly, lichenified, and hairless (Fig. 17-58). Microscopically, early lesions consist of superficial perivascular dermatitis with eosinophils, mast cells, and lymphocytes. Mild focal spongiosis can be seen. Small parakeratotic crusts can develop as spongiotic lesions age. Chronic lesions are associated with epidermal acanthosis with marked rete ridge formation, compact hyperkeratosis, parakeratosis, crusting, and perivascular dermatitis with eosinophils, mast cells, and lymphocytes. In areas of excoriation, neutrophils—and with time, dermal scarring—may be evident. Mites, mite eggs, or feces may be found in tunnels in the stratum corneum (Fig. 17-58), but are not commonly seen in tissue sections because of small numbers of mites.

**Fig. 17-58 *Sarcoptes scabiei* infestation, skin, dog.** **A**, Ear. Note the alopecia, erythema, and scaling along the margin of the ear. **B**, Note the section of a mite in the stratum corneum. The epidermal hyperkeratosis, acanthosis, and rete ridge formation are in response to both the mite itself and also to self-trauma caused by intense pruritus. H&E stain. (**A**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.2.3.5.2.3

### Notoedric mites

Notoedric mite infestation is caused by *Notoedres cati*. This mite infests cats, rabbits, and occasionally foxes, dogs, and human beings. It is a rare but highly contagious pruritic disease characterized initially by an erythematous papular rash followed by scales, crusts, and alopecia, and, when chronic, with lichenification. Lesions begin on the neck and pinnae and extend to the head, face, and paw and can become generalized. Microscopic lesions consist of a hyperplastic, perivascular eosinophilic dermatitis with mild spongiosis, and crusts. In cats, mites are readily found in the stratum corneum in tissue sections or in skin scrapings.

1199

1200

17.2.3.5.2.4

### Otodectic mites

Otodectic mite infestation caused by *Otodectes cynotis* occurs in the external ear canals of dogs and cats and occasionally can be present on other parts of the body. The mite lives on the skin surface and can be seen by direct visualization. Because *Otodectes* can be present in areas of the body other than ears, it is important to differentiate it from *Sarcoptes* and *Notoedres* mites, which can be identified in microscopically examined skin scrapings or sometimes in tissue sections.

17.2.3.5.2.5

### Psoroptic mites

Psoroptic mite infestation in sheep, cattle, horses, goats, rabbits, and other animals is caused by several species of host-specific mites. *Psoroptes cuniculi* live on the surface of the skin, feeding on lipids and later on serous and hemorrhagic crusts that exude from the traumatized skin. It infests the external ear canals of rabbits, horses, goats, and sheep. *Psoroptes equi* infests the base of the mane and tail, and skin under the forelock of horses. *Psoroptes ovis* causes serious disease in cattle and sheep, producing parasitic lesions of thickened skin and dry scales and crusts that begin on the withers and spread because of persistent self-inflicted trauma. In sheep, psoroptic mite infestation is called “sheep scab.” Lesions develop on the withers and sides. The woolled areas are chiefly involved with crusts that become adherent to the matted fleece and in time expand and coalesce. Damage is due to self-inflicted trauma, resulting from the pruritus associated with irritation and hypersensitivity reactions. The microscopic lesion is a spongiotic, hyperplastic, hyperkeratotic, or exudative superficial perivascular dermatitis with eosinophils. Self-trauma leads to erosions, ulcers, and exudation of serum and leukocytes. No cases of *Psoroptes ovis* have been reported in sheep in the United States since 1970.

17.2.3.5.2.6

### Chorioptic mange

Chorioptic mange, caused by *Chorioptes bovis*, affects cattle, horses, goats, and, in some countries, sheep. The mite is not host specific. Mites on the skin surface cause irritation and pruritus leading to self-trauma and the gross lesions of erythematous, papular, crusted, scaly, hairless, thickened skin on the lower hind limbs, scrotum, tail, perineum, udder, and thigh of cattle; lower limbs of horses; scrotum and lower hind limbs of sheep; and lower limbs, hindquarters, and the abdomen of goats. Microscopic lesions are similar to those seen in other surface-dwelling mite infestations.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.2.3.5.2.7

### Cheyletiellosis

Cheyletiellosis, caused by infestation with *Cheyletiella* sp., occurs in dogs, cats, rabbits, wild animals, and human beings. The mite lives on the surface of the skin and induces hyperkeratosis. In dogs and cats, lesions consist of hyperkeratosis manifested as dry, white, scaly dandruff along the dorsal midline of the back. Some infestations are asymptomatic. Cats can have focal, multifocal, to generalized red papules or crusts, characterized microscopically by superficial perivascular dermatitis with eosinophils. The diagnosis requires identification of the mites via skin scrapings, acetate tape, or brush techniques because mites are not usually seen in tissue sections.

17.2.3.5.2.8

### Psorergatic mites

Psorergatic mite infestation, caused by *Psorergates ovis*, occurs in sheep in Australia, New Zealand, South Africa, and Argentina. Sheep in the United States have been free of *Psorergates* sp. mites since 1973. Suspected cases of psorergatic mange should be reported to the state veterinarian. The infestation initially results in papules and scales along the trunk. Over time, the fleece becomes ragged as severe pruritus leads to secondary crusts, lichenification, and hyperpigmentation with alopecia.

17.2.3.5.2.9

### Trombiculiasis

Trombiculiasis is infestation by larvae of trombiculid (harvest) mites also known as chiggers. *Eutrombicula (Trombicula) alfreddugesi* (North American chigger), and *Eutrombicula (Trombicula) splendens* are some of the species implicated in trombiculiasis in cats, dogs, and horses. *Neotrombicula (Trombicula) autumnalis*, the European harvest mite, attacks most domestic species. *Eutrombicula (Trombicula) sarcina*, an Australian species known as the leg-itch mite, is an important parasite of sheep, although its principal host is the gray kangaroo. The larvae tunnel into the epidermis and inject saliva that gels to form a characteristic stylostome used to obtain digested tissue fluids. Grossly, small red papules or crusts containing several orange to red larvae develop on parts of the skin in close contact with plants or the ground. Lesions are intensely pruritic. The microscopic lesions are a hyperplastic, superficial perivascular dermatitis with eosinophils, mast cells, and intraepidermal mites. Identification of a stylostome microscopically is pathognomonic.

17.2.3.5.3

### Ticks

Ticks comprise two families, Ixodidae (hard ticks that contain a scutum, a hard chitinous plate on the anterior dorsal surface) and Argasidae (soft ticks that lack the scutum). Most of the pathogenic ticks are in the family Ixodidae. An exception is *Otobius megnini*, the spinose ear tick, which is parasitic to all domestic animals and causes severe otitis externa. Heavy tick infestations, particularly by adult argasid ticks that engorge repeatedly, can cause anemia. As obligate bloodsucking ectoparasites, ticks also serve as vectors for many potentially severe blood-borne diseases, such as *Rickettsia rickettsia* (Rocky Mountain spotted fever), *Borrelia burgdorferi* (Lyme disease), *Anaplasma marginale* (anaplasmosis), and African swine fever. Tick bites also cause direct damage to the skin at the site of attachment, which predisposes to secondary bacterial infection leading to abscesses or septicemia, and to myiasis. Adverse reactions to ticks depend in part on the content of salivary secretions. Tick saliva has been shown to contain factors that are antihemostatic, antiinflammatory, and immunosuppressive; a key factor contributing to these functions is prostaglandin E<sub>2</sub>. These factors are thought to facilitate feeding and the

1200

1201

## Pathologic Basis of Veterinary Disease, 4th Edition

---

transmission of tick-borne diseases. In addition, salivary secretions of several species of ixodid ticks (e.g., *Dermacentor andersoni* and *Dermacentor variabilis* in North America) contain neurotoxins that can cause an acute ascending lower motor neuron paralysis of the host. If the tick is removed, symptoms disappear rapidly.

The severity of local cutaneous reactions varies not only with salivary secretions, but also with host resistance. In experimental studies, it has been shown that in nonsensitized hosts, the inflammatory response to tick mouth parts embedded deeply in the dermis develops in the immediate site of the bite, is composed largely of neutrophils, and is minor even about 2 days after the tick attaches. In contrast, previously sensitized hosts develop more rapid and intense local reactions (as early as 1 hour postattachment). Cutaneous lesions are present a greater distance from the site of attachment, and basophils, eosinophils, and neutrophils are present in the epidermis and dermis. Cutaneous basophil hypersensitivity, a form of delayed-type hypersensitivity, plays an important role in immunity to ticks.

In naturally occurring cases, gross lesions include red papules that progress to circular erythematous areas up to 2 cm in diameter. Lesions progress to foci of necrosis, erosions, ulcers, crusts, and in some animals, nodules. Lesions heal with scarring and alopecia. Histologic lesions include congestion, edema, and sometimes hemorrhage with an intradermal cavity below which the tick mouthparts may be present. Inflammation consists of perivascular to diffuse accumulations of neutrophils, eosinophils, and basophils. Later developing lesions include epidermal and dermal necrosis, the granulocytic leukocytes of more acute lesions plus accumulations of lymphocytes and macrophages at the margin of the necrotic dermis. In a cross section of skin, these lesions can be triangular with the apex at the panniculus. Some lesions comprise granulomas (arthropod bite granulomas) in which the inflammatory cells efface the tissue architecture and lymphoid follicles form.

### 17.2.3.5.4

#### Lice

Pediculosis is infestation with lice and is caused by two orders of lice: Mallophaga (biting lice) and Anoplura (blood-sucking lice). Infestations are relatively host specific, are spread by direct contact, and are relatively easy to control because the life cycle takes place entirely on the host. Pediculosis occurs more commonly in winter when temperatures are cooler, the wool or hair coat is longer, animals are congregated, and the plane of nutrition is lower. Thus heavy infestations are usually an indication for underlying problems, such as overcrowding, poor sanitation, or poor nutrition. Generally, pediculosis is not a significant threat to the host, and animals with low infestations may not have clinical signs or lesions. Most problems are related to skin irritation and resultant pruritus. However, the Anoplura have piercing mouth parts and suck blood, thus heavy infestations can cause anemia. In addition, *Haematopinus suis*, a sucking louse that parasitizes pigs, is economically important because the lice transmit *Eperythrozoon suis*, and the viruses of swinepox and African swine fever. The Mallophaga cause less severe signs as they feed on epithelial cellular debris. Primary lesions caused by lice are few, and most are secondary to scratching, rubbing, or biting. The cause of the pruritus is not known, but is thought to be a result of more than mechanical irritation alone. Gross lesions consist of papules, crusts, excoriations, and damage to hair, wool, or skin. Lice and eggs are visible on hair or wool. Animals infested with sucking lice can be anemic. Weight loss and reduced production of milk can result from the constant irritation associated with some infestations.

### 17.2.3.5.5

#### Fleas

Flea infestation is principally a problem in dogs and cats. *Ctenocephalides felis* is the most common flea causing infestation, and it also transmits *Dipylidium caninum*. Infestation can occur with *Ctenocephalides canis*, and less commonly with fleas that parasitize other mammals and birds. Fleas can cause severe skin irritation because of frequent biting and release of enzymes, anticoagulants, and histamine-like substances, hypersensitivity reactions to saliva, and secondary host-inflicted trauma from scratching and biting. Severe infestations can cause blood loss (anemia), especially in puppies, kittens, or small debilitated adults. Lesions occur over the dorsal lumbosacral region (Fig. 17-59), caudomedial thighs, ventral abdomen, flanks, and, in cats the neck area, and consist of multiple red papules and secondary excoriations (see insect bite hypersensitivity section).

1201

1202

**Fig. 17-59 Insect bite hypersensitivity, skin, acute moist dermatitis (pyotraumatic dermatitis), dog. A, Flea bite hypersensitivity.** The hair has been clipped to allow better visualization of the lesions. Self-inflicted trauma is largely the source of the erosion, moist exudation, and crusting in the skin of this dog with flea bite hypersensitivity. **B, Insect bite.** The serocellular crust on the epidermal surface covers a defect in epidermis, beneath which in the dermis is a vertical zone of necrosis infiltrated by eosinophils (arrow). Hypersensitivity reactions to insect bites can be pruritic and initiate scratching and result in acute moist dermatitis. H&E stain. (A, Courtesy Dr. Ben Baker, Washington State University. B, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.2.3.5.6

#### Flies

Cutaneous reactions due to fly bites range from minor to severe, and are due to bites by adult flies and to myiasis by larvae. Reactions to the bites of flies vary and include irritation, anemia, direct toxicity, and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

hypersensitivity. Biting flies include *Haematobia irritans* (horn fly), *Stomoxys calcitrans* (stable fly), and horse flies, deer flies, black flies, biting gnats, mosquitoes, and the sheep ked (*Melophagus ovinus*), a common wingless fly that sucks blood. Lesions of biting flies are due to local irritation and include wheals and papules centered around a puncture wound that can bleed. Such lesions can persist with hair loss, scales, hemorrhagic crusts, erythema, and secondary excoriations because of self-inflicted trauma, especially if the animals are hypersensitive to the bites. Such hypersensitivity occurs with *Culicoides* sp. in horses (Queensland itch, sweet itch; see Selected Hypersensitivity Reactions, Culicoides Hypersensitivity) and mosquitoes in cats (see Selected Hypersensitivity Reactions, Mosquito Bite Hypersensitivity in Cats). Microscopic lesions associated with fly bites vary depending on the fly involved. Dermal hemorrhage and edema with a central area of epidermal necrosis are early lesions seen with bites of some flies. Hemorrhagic crust covers areas of necrosis, and perivascular neutrophilic, eosinophilic, and mixed mononuclear inflammation can be seen. Intraepidermal eosinophils including eosinophilic pustules are sometimes identified, and eosinophilic folliculitis and furunculosis can be present in reactions to mosquito bites. Epidermal hyperplasia, hyperkeratosis, parakeratosis, and crusting are associated with self-trauma.

Myiasis is infestation of tissues by the larvae of dipterous flies (flies with two wings or winglike appendages), and is a disease of neglect. Lesions develop in skin kept moist and soiled by urine, feces, or body secretions. Flies are attracted by the odor of such areas. Sheep, largely because of ovine fleece rot (see Superficial Bacterial Infections) are most commonly affected. In myiasis caused by blow flies (calliphorids) and flesh flies (sarcophagids), eggs are deposited in wounds or on soiled hair or wool. Gross lesions consist of matted hair or wool and multiple irregular cutaneous holes or ulcers with an offensive odor. Secretion of proteolytic enzymes by larvae causes lesions to spread. Death can result, and is due to septicemia or toxemia.

In cuterebral myiasis, eggs of *Cuterebra* sp. are deposited on stones or vegetation near the burrows of rabbits and rodents, the natural hosts. Less often cats or dogs become infested. The eggs hatch to first-stage larvae on the vegetation, and when the host contacts the vegetation, larvae attach to the hair coat and move to the skin. Once on the skin, larvae move to natural body openings such as the nares, where they penetrate the mucosa. Other portals of entry are direct penetration of the skin or ingestion by the host during grooming. The larvae migrate to the subcutis, produce a cyst-like subcutaneous nodule in which the larvae mature and cut a hole in the skin for respiration. The larvae feed on tissue debris. Wounds heal slowly after larvae are removed or released, but secondary bacterial infection can develop.

1202

1203

In hypoderma myiasis, larvae of *Hypoderma lineatum* and *Hypoderma bovis* penetrate the skin of the legs of cattle and less frequently horses and migrate proximally in the subcutis of the leg. The larvae can be found in many areas of the body. After weeks to months, first-stage larvae reach the esophagus (*Hypoderma lineatum*) or vertebral canal (*Hypoderma bovis*) where they develop into second-stage larvae. These second-stage larvae then migrate to the subcutis of the back, become established in subcutaneous nodules similar to those of *Cuterebra* sp. with an opening for respiration, and mature to third-stage larvae (Fig. 17-60). Microscopically, these larvae are located in a cavity filled with fibrin and a few eosinophils and bordered by granulation tissue containing clusters of eosinophils.

Screwworm myiasis is caused by two species of Diptera larvae, *Cochliomyia hominivorax* (Coquerel) the New World screwworm, and *Chrysomya bezziana* (Villeneuve), the Old World screwworm. *Cochliomyia hominivorax* occurs in tropical and semitropical regions of the Western hemisphere including Central and South America and some Caribbean islands. It has been eradicated in the United States and Mexico. *Chrysomya bezziana* (Villeneuve) is found in tropical and semitropical regions of the Eastern Hemisphere including Africa and Southern Asia. Screwworm flies deposit eggs in wounds or

## Pathologic Basis of Veterinary Disease, 4th Edition

near mucocutaneous junctions of living animals. The eggs develop into first-stage larvae that move into the wound. Larvae have sharp, pointed mouth hooks that tear living tissue. Larvae feed on tissues liquefied by secretions of proteolytic enzymes. Screwworm myiasis is an important disease in domestic and wild animals because screwworm larvae destroy viable tissue. Grossly, malodorous wounds contain larvae, shreds of tissue, and copious amounts of reddish-brown fluid. Once an animal is infested, death is almost inevitable unless the larvae are removed. When it is necessary to differentiate screwworm myiasis from cutaneous myiasis caused by other flies, larvae can be preserved in 70% alcohol and submitted for identification. Screwworm myiasis is a reportable disease in some countries, including the United States.

**Fig. 17-60 Myiasis, skin, subcutis. A, Hypodermal myiasis, *Hypoderma* sp. larva, cow. Multiple nodules each contain a single larva. One nodule (right) has been incised to expose a larva (arrow). B, Cuterebral myiasis, *Cuterebra* sp. larva, dog. Note a portion of a subcutaneous cystic nodule that contains a segment of a larva (arrow). The panniculitis is largely comprised of eosinophils. H&E stain. (A and B, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)**

Larvae of the tropical warble fly, *Dermatobia hominis*, cause cutaneous myiasis in numerous species of mammals, most commonly and importantly in cattle, in South and Central America. Adult *Dermatobia hominis* attaches its eggs to the legs of other insects that then transport the eggs to the mammalian hosts. While the insects feed, the eggs are deposited on the skin, hatch into larvae, and quickly penetrate the skin of the host mammal. The larvae grow in subcutaneous nodules similar to those of *Cuterebra* sp. with an opening on the skin surface for respiration, after which they leave the nodule and drop to the ground to complete their life cycle. *Dermatobia* myiasis is of economic importance because it causes condemnation of hides at slaughter and predisposes the skin to myiasis by other flies.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

17.2.3.5.7

### Helminths

Cutaneous infections with helminths are generally not life threatening but can be unsightly and irritating in companion animals and cause hide damage in food animals. Infections are due to migration of helminth larvae that as adults live in noncutaneous sites, or by filarial infections (filarial dermatitis) in which adults or microfilaria spend some time in the skin or subcutis.

17.2.3.5.7.1

### Helminth larval migrans

17.2.3.5.7.1.1

#### Hookworm dermatitis.

Hookworm dermatitis is caused by cutaneous migration of the larvae of *Ancylostoma* or *Uncinaria* sp. Red papules that coalesce and develop into lichenified alopecic areas occur on the feet of dogs and, less frequently, on other areas in contact with an unsanitary environment contaminated by hookworm larvae. Footpads can become soft, the keratinized portion can separate, and secondary bacterial dermatitis and paronychia can develop. Hyperplastic spongiotic perivascular dermatitis with eosinophils, serocellular crusts, and migration tracks are the microscopic lesions. Parasitologic evaluation of fresh tissue may allow larval identification.

1203

17.2.3.5.7.1.2

#### Cutaneous habronemiasis.

1204

Cutaneous habronemiasis (summer sores) occurs in horses and is caused by infection with the larvae of *Habronema* sp. or *Draschia* sp. deposited on the skin by house or stable flies. Larval deposition and lesions occur on parts of the body where the skin is either traumatized, such as the legs, or moist and soft, such as the prepuce and medial canthus of the eye (Fig. 17-61). Larvae are unable to penetrate normal skin, but fly bites cause sufficient damage to allow larval penetration. Grossly, single or multiple, proliferative, ulcerated red to brown, nodular masses are present that on section have small, yellow to white, gritty foci. The microscopic lesion is a nodular dermatitis with eosinophils, epithelioid macrophages, and, sometimes, giant cells bordering larvae or necrotic debris (Fig. 17-61, B). Granulation tissue infiltrated by neutrophils is present on the ulcerated surface.

Other helminth parasites associated with cutaneous larval migration include *Pelodera*, *Necator*, *Strongyloides*, *Gnathostoma*, and *Bunostomum*. Schistosome cercariae, especially of birds, can cause similar lesions.

17.2.3.5.7.1.3

#### Filarial dermatitis.

Onchocerciasis is a filarial dermatitis principally affecting horses. Adult parasites are located in nodules in connective tissue and can be asymptomatic. Microfilariae are located in the dermis, particularly of the ventral midline, and are the source of the major lesions. Intermediate hosts, such as the Simuliidae (black flies, gnats) and Ceratopogonidae (biting midges), transmit the microfilariae. Not all horses with microfilariae have clinical signs or lesions. In those horses with cutaneous inflammation attributed to microfilariae, dead or dying microfilariae induce the most intense inflammation, and inflammation can be enhanced by microfilaricidal therapy. Differences in lesion severity between horses may reflect different degrees of hypersensitivity to microfilariae,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

different degrees of hypersensitivity to the bites of intermediate hosts, or possibly other factors. Recent evidence in human filarial disease has revealed that the acute inflammatory response in two important diseases, elephantiasis and river blindness, may largely be a result of the endosymbiotic bacteria (*Wolbachia*) harbored within the filarial parasites and released into the blood by living parasites or following death or damage of the adults or microfilariae. The inflammatory stimulus is thought to be caused by endotoxin-like activity that is dependent on pattern recognition receptors known to contribute to innate immunity. *Wolbachia* have been identified in a number of filarial parasites in animals including *Onchocerca gutturosa*, *Onchocerca lienalis*, and *Onchocerca cervicalis*. However, further research is needed to determine the role, if any, of these bacteria in filarial parasitic diseases in animals. In equine onchocerciasis, clinical lesions related to microfilariae develop on the head, neck, medial forelimbs, ventral thorax, and abdomen, and consist of patchy to diffuse alopecia, erythema, scaling, crusting, and pigmentary changes. Some horses have a characteristic, variably pigmented, circular area of dermatitis on the forehead. Keratitis, conjunctivitis, and uveitis are observed in some horses. Microscopic cutaneous lesions vary from none to superficial and deep perivascular to interstitial dermatitis with eosinophils, lymphocytes, and microfilariae. Fibrosis is seen in older lesions.

1204

1205

Fig. 17-61 **Cutaneous habronemiasis, *Habronema* sp., skin, horse.**

**A**, Face. Multiple coalescing nodular granulomatous and ulcerated areas are present on the skin of the medial canthus, skin immediately ventral to the eye, and the skin of the lateral surface of the face. Lesions of cutaneous habronemiasis develop in areas of the skin that are traumatized (often the legs) or in soft moist skin (around the genitalia or eyes). In this case, moisture from ocular secretion (tears) may have predisposed to bites of house or stable flies, with subsequent emergence and migration of *Habronema* sp. larvae into the dermis. **B**, Note sections of larvae (arrow) within nodule of granulomatous and eosinophilic dermatitis. H&E stain. *Inset*: The inset illustrates eosinophils in the inflammatory response. H&E stain. (**A**, Courtesy Dr. Valerie Fadok, College of Veterinary Medicine, University of Florida. **B** and *Inset*, Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Stephanofilariasis, a filarial dermatitis of cattle, buffalo, and goats, is transmitted by flies and caused by six species of parasites of the genus *Stephanofilaria*. Each species of *Stephanofilaria* causes lesions in a different body location. Cutaneous lesions are caused by a reaction to the parasites free in the dermis, to the bites of the flies serving as the vector, and self-inflicted trauma. *Stephanofilaria stilesi* occurs in cattle in the United States and causes lesions along the ventral midline that consist initially of small (1 cm) circular patches with moist erect hairs, foci of epidermal hemorrhage, and serum exudation. Such foci expand and coalesce into a large area covered by crusts, which upon healing, consist of thickened hairless plaques as large as 25 cm in diameter (Fig. 17-62). Microscopic lesions consist of superficial and deep perivascular dermatitis with eosinophils, epidermal hyperkeratosis, parakeratosis, acanthosis with spongiosis, eosinophilic microabscesses, and crusts. Adult parasites and microfilaria can be seen. Other causes of filarial dermatitis include *Elaeophora* sp., *Parafilaria* sp., *Suifilaria* sp., and rarely *Dirofilaria* sp. or *Acanthocheilonema* sp.

17.2.3.5.8

### Protozoa

In the United States, cutaneous protozoal infections develop as part of systemic infections, principally with members of the genus *Leishmania*. Rarely, cutaneous infection with *Caryospora* sp., *Neospora* sp., *Sarcocystis* sp., or *Toxoplasma* sp. has been reported. Leishmaniasis occurs in human beings, dogs, cats, horses and other mammals. Members of the *Leishmania donovani* complex, an intracellular parasite of the mononuclear-phagocytic system, cause most infections. Sandflies serve as the vector for infection of animals. Dogs, cats, and rodents serve as reservoirs of infection for human beings. Leishmaniasis is endemic in Mediterranean countries and some parts of Africa, India, and Central and South America. The disease, which can occur in cutaneous, mucocutaneous, or visceral forms, is rare in animals in the United States except in endemic areas in Oklahoma, Texas, and Ohio. However, visceral leishmaniasis has been identified recently in about 21 states in the United States and in southern Canada, indicating an increase in the prevalence of this disease. Infections in animals in the United States also have been associated with foreign travel of human beings and their animals.

Fig. 17-62 **Stephanofilarial dermatitis, *Stephanofilaria stilesi*, skin, cow.** **A**, Ventral abdomen. Note the thickened plaquelike area of alopecia and lichenification. **B**, Note longitudinal and cross sections of adult parasite. The adult parasites usually live in a cystlike space at the base of a hair follicle (*arrow*) and can destroy follicles. Note the marked infiltrate of mixed mononuclear cells around the cystic space and base of the follicle (perifolliculitis). H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida.)

The skin is one of the main organs affected in systemic leishmaniasis in dogs. Resistance to infection is dependent upon a  $CD4^{+} T_H1$  lymphocyte immune response, and lesion severity and character vary with host immune response and concurrent disease. Dogs with the alopecic form of the cutaneous disease have fewer organisms and a more robust cellular immune response including larger numbers of antigen-presenting Langerhans' cells, MHC II-positive keratinocytes, and infiltrating T lymphocytes. In contrast, dogs with the nodular form of cutaneous disease have fewer antigen-presenting cells and greater numbers of macrophages and larger numbers of organisms. Therefore it has been suggested that the clinical and histologic lesions can be useful in establishing a prognosis for remission, in that the character of the lesions reflects immune competence. Cutaneous lesions in dogs consist of generalized alopecia with silvery white scales, or more severe lesions of nodules and ulcers. Lesions occur chiefly in anatomic areas where sandflies feed—around the muzzle (nose), ears, and eyes. Paronychia and deformed claws have also been reported. Microscopically, lesions include hyperkeratosis, parakeratosis, crusts, and granulomatous nodules in the dermis including periadnexal regions. Accumulations of macrophages, lymphocytes, and plasma cells can efface sebaceous glands. *Leishmania* sp. are most

## Pathologic Basis of Veterinary Disease, 4th Edition

commonly identified within macrophages, however, they can occasionally be found within other leukocytes, endothelial cells, or fibroblasts. In areas of necrosis, the organisms can be free within the interstitium. *Leishmania* sp. can be distinguished from other protozoa via light microscopy by recognizing the kinetoplast oriented perpendicular to the nucleus. Cytology, immunohistochemistry, PCR, and serologic testing can help confirm the diagnosis.

1205

### 17.2.4 IMMUNOLOGIC SKIN DISEASES

1206

Immunologic diseases are classified as either hypersensitivity (allergic) or autoimmune. Hypersensitivity is a mild to severe reaction that develops in response to normally harmless foreign compounds including antiserum, pollen, and insect venoms. In contrast, autoimmune diseases develop when antibodies or T lymphocytes react against self-antigens, rather than against foreign antigens. "Autoimmune disease" in this section is a general term referring to a spectrum of diseases in which autoimmune mechanisms appear to participate in lesion production. Four basic immune reactions, types I, II, III, and IV, mediate the tissue damage in both hypersensitivity and autoimmune diseases (Table 17-11). Most cutaneous hypersensitivity reactions are mediated either by type I or type IV reactions, or by a combination of one or more of the four reactions. Autoimmune mechanisms tend to be mediated by type II or III reactions, although more than one mechanism can be involved. Hypersensitivity reactions are common in dogs and horses, less common in cats, and are uncommon in food animals. Autoimmune diseases with cutaneous manifestations are uncommon in domestic animals, accounting for 1% to 2% of dermatoses in most species. Of the cutaneous autoimmune disorders, pemphigus foliaceus is the most prevalent, followed in incidence by discoid and systemic lupus erythematosus. In domestic animals, certain breeds of dogs, horses, and cats seem to be predisposed to develop particular autoimmune diseases.

#### 17.2.4.1 MECHANISMS OF TISSUE DAMAGE IN HYPERSENSITIVITY REACTIONS

##### 17.2.4.1.1 Type I Hypersensitivity Reactions

These inflammatory reactions are mediated by preformed or newly synthesized pharmacologically active substances released by mast cells and basophils following reaction between foreign antigen and specific antibody (usually IgE) bound to high affinity IgE receptors on the membrane of the mast cells or basophils (Table 17-11). Preformed substances released from mast cells include histamine, factors chemotactic for eosinophils and neutrophils, prostaglandins, serine esterases, and TNF- $\alpha$ . Substances synthesized upon mast cell stimulation include leukotrienes, cytokines, and platelet-activating factor. Type I hypersensitivity can be systemic (anaphylaxis), localized to the skin, or both. In the skin, the reaction results clinically in pruritic, circumscribed wheals with raised, erythematous borders. The reaction occurs in two phases, immediate (15 to 30 minutes) and late (6 to 12 hours), and is generally referred to as an immediate hypersensitivity reaction. The eosinophil products, major basic protein and eosinophil cationic protein, are toxic to epithelial cells and contribute to tissue damage in the late-phase reaction. The production of IgE is genetically controlled, and therefore inherited predispositions to type I hypersensitivity occur. Cutaneous type I hypersensitivity reactions include atopic dermatitis (most common), urticaria, angioedema, hypersensitivity resulting from bites of flies such as *Culicoides* sp. and mites such as *Sarcoptes* sp., the presence of gastrointestinal parasites, and ingested dietary components (proteins, grains, preservatives, and so on). This type of reaction is characterized microscopically by mast cell degranulation, capillary dilation, edema, and infiltrates of eosinophils.

17.2.4.1.2

### Type II Hypersensitivity Reactions

Type II hypersensitivity reactions, also called “cytotoxic reactions,” are dependent on IgG or IgM antibodies formed against either normal or altered cell membrane antigens. The reaction engages Fc receptor and complement-mediated effector mechanisms. Cell damage occurs by either complement-mediated lysis, antibody-dependent cell-mediated cytotoxicity, or antibody-directed cellular dysfunction ([Table 17-11](#)). The first two mechanisms are most common in type II reactions affecting the skin. Examples include deposition of autoantibody to desmogleins 1 and 3, transmembrane proteins found in desmosomes that provide physical connections between keratinocytes and are present in pemphigus (uncommon), and autoantibody to bullous pemphigoid antigen 2, a 180 kD hemidesmosomal transmembrane molecule in bullous pemphigoid (rare). The lesions vary with the location of the target antigen. In pemphigus foliaceus, desmosomal damage leads to formation of superficial epidermal vesicles that rapidly become pustules and crusts, whereas in bullous pemphigoid the deeper hemidesmosomal damage leads to formation of subepidermal vesicles that rapidly become ulcers.

17.2.4.1.3

### Type III Hypersensitivity Reactions

Type III reactions are mediated by soluble immune complexes mostly of the IgG class formed in the circulation or in tissues. The antigen can be exogenous (e.g., bacterial) or endogenous (organ specific as in systemic lupus erythematosus). Immune complexes are often deposited in vessel walls and result in complement fixation and in the generation of cytokines and leukotactic factors, leading to vasculitis ([Table 17-11](#)). Tissue damage results from lysosomal enzymes released from neutrophils, activation of complement and coagulation systems, platelet aggregation, and free oxygen radicals. Immune-complex vasculitis is believed responsible for the purpura seen in infections in horses with *Streptococcus equi*, and is responsible for some of the lesions of systemic lupus erythematosus. Clinical lesions associated with immune-complex vascular damage include hemorrhages with serum exudation. Microscopic lesions consist of the vascular wall disrupted by neutrophils (neutrophilic vasculitis), perivascular edema, hemorrhage, and fibrin exudation.

1206

1208

## Pathologic Basis of Veterinary Disease, 4th Edition

**Table 17-11 Mechanisms of Tissue Damage in Hypersensitivity or Autoimmune Diseases**

There are four types of hypersensitivity reactions (type I, II, III, IV) that cause tissue damage by immunologic mechanisms. Types I, II, and III are mediated by antibodies and are distinguished by the type of antigen and class of antibody involved. Type I responses are mediated by IgE bound to the high-affinity IgE receptor on the surface of mast cells. Binding of foreign (exogenous) antigen to IgE cross-links these receptors, inducing mast-cell activation. Type II responses are mediated by IgG or IgM directed to antigens bound to the surface of the cell or part of cell membrane. The reaction can engage Fc receptor and complement-mediated effector mechanisms. Type III responses are mediated by IgG or IgM directed against soluble antigens, and the tissue damage is caused by responses triggered by immune complexes. Type IV hypersensitivity reactions are mediated by T lymphocytes and can be subdivided into three groups. In the first group, tissue damage is caused by CD4+T<sub>H</sub>1 lymphocytes directed to soluble antigen bound to MHC II and that release cytokines including IFN- $\gamma$ , resulting in an inflammatory response via macrophage activation. In the second, damage is caused by activation by CD4+T<sub>H</sub>2 (helper) lymphocytes directed to soluble antigen bound to MHC II and that release IL-4 and IL-5, resulting in an inflammatory response in which eosinophils predominate. In the third, damage is caused by cytotoxic T lymphocytes (CD8+) directed to cell-associated antigen bound to MHC I.

	Type I	Type II	Type III	Type IV		
Immune reactant	IgE	IgG or IgM	IgG or IgM	CD4+ lymphocyte, T <sub>H</sub> 1 type	CD4+ Lymphocyte, T <sub>H</sub> 2 type (T-helper)	CD8+ cytotoxic lymphocyte
Time frame	15–30 min	Minutes to hours	3–10 hr	48–72 hr	48–72 hr	48–72 hr
Antigen	Exogenous antigen	Antigen is bound to surface of cell or is a part of the cell membrane	Soluble antigen, endogenous or exogenous	Soluble antigen bound to MHC II— injected into skin	Soluble antigen bound to MHC II	Cell-associated antigen bound to MHC I
(Examples)	(pollens, molds, insect salivary antigens)	(desmosomal or hemidesmosomal proteins)	(DNA, histones, ribosomes) ( <i>Streptococcus equi</i> )	(tuberculin)	(atopic dermatitis; mites, pollens)	(contact antigen or self-antigen)
Effector mechanism	Mast cell activation	FcR+ cells (macrophages, NK cells) complement	FcR+ cells complement	Macrophage activation	Eosinophil activation	Cytotoxicity
						
Examples of hypersensitivity	Atopic dermatitis, urticaria, anaphylaxis	Pemphigus, pemphigoid	Systemic lupus erythematosus  Purpura in <i>Streptococcus equi</i> infection	Diagnosis of infections by <i>Mycobacteria</i> spp. and systemic fungal infections	Atopic dermatitis	Contact hypersensitivity  Graft-versus-host disease

### 17.2.4.1.4 Type IV Hypersensitivity Reactions (T-Lymphocyte–Mediated Hypersensitivity Reactions)

Type IV reactions are mediated by antigen-specific effector T lymphocytes. These include sensitized  $CD4^+$  lymphocytes ( $T_H1$  or  $T_H2$ ), or  $CD8^+$  lymphocytes (cytotoxic T lymphocytes) (Table 17-11). The reaction mediated by sensitized  $CD4^+$   $T_H1$  cells develops after contact with a specific persistent or nondegradable antigen (such as tuberculin), causing the release of cytokines and recruitment of other lymphocytes and macrophages. The reaction is largely dependent on IFN- $\gamma$  or other cytokines including IL-2. IFN- $\gamma$  activates macrophages that work to eliminate the targeted antigen. In reactions mediated by  $CD4^+$   $T_H2$  lymphocytes (T-helper cells), contact with soluble antigen bound to MHC II results in inflammatory responses in which eosinophils predominate. This type of reaction is believed to participate in the pathogenesis of atopic dermatitis. In the cytotoxic reaction, the  $CD8^+$  T lymphocytes kill the targeted host cell directly. This is the mechanism of damage associated with allergic contact dermatitis associated with antigens such as poison ivy and can also participate in graft-versus-host disease. Type IV reactions take many hours to develop and are initiated by antigens bound to host cell major histocompatibility molecules. Type IV reactions mediated by  $CD4^+$   $T_H1$  cells are used in the diagnosis of diseases such as tuberculosis, histoplasmosis, and coccidioidomycosis. The skin reaction typically develops 24 to 48 hours after exposure to the specific antigen and consists of perivascular mononuclear cell accumulations and dermal edema.

### 17.2.4.1.5 Combination Hypersensitivity Reactions

The strict categorization of hypersensitivity reactions is an oversimplification. Categories and lesions can overlap, and there are species differences. Hypersensitivity to fleas, ticks, *Staphylococcus* sp., hormones, and drugs are mediated by a combination of types I, II, III, or IV reactions. Therefore histopathologic examination may provide the general category of inflammatory reaction pattern and rule out other disease processes but may not lead to a diagnosis of the specific type of hypersensitivity present.

### 17.2.4.2 SELECTED HYPERSENSITIVITY REACTIONS

#### 17.2.4.2.1 Urticaria and Angioedema

Urticaria (hives) and angioedema occur most commonly in dogs and horses, and consist of multifocal or localized areas of edema. In urticaria, the edema involves the superficial dermis, whereas in angioedema, the edema involves the deep dermis and subcutis. There are immunologic (foods, drugs, antisera, insect stings) and nonimmunologic (heat, exercise, stress) stimuli. Immunologic mechanisms involve type I and type III hypersensitivity reactions. A unique form of urticaria has been described in Jersey and Guernsey cattle because of a type I hypersensitivity reaction to casein in their milk. Urticarial lesions are wheals that typically arise suddenly and remain a few hours, although chronic urticaria (lasting weeks or longer) has been described. In some animals, serum oozes from the wheals matting the hair coat. Angioedema is a localized or generalized area of extensive deep dermal and subcutaneous edema. Histologic lesions in urticaria and angioedema are subtle and consist of vascular dilation and edema with or without perivascular eosinophilic to mixed mononuclear dermatitis. Occasionally, the intercellular epidermal edema (spongiosis) progresses to epidermal vesicles, serum exudation, and serous crusting.

### Atopic Dermatitis (Atopy, Allergic Inhalant Dermatitis)

Atopic dermatitis is defined as a genetically predisposed inflammatory and pruritic allergic skin disease with characteristic clinical features associated most commonly with IgE antibodies to environmental allergens. It is an example of a type I hypersensitivity reaction, although type IV mechanisms also participate. The skin is the major target organ in dogs, cats, and horses. The route of allergen exposure is controversial, and traditionally has been considered to be respiratory. However, percutaneous absorption may be the major route of exposure, at least in dogs. Atopy is the second most common hypersensitivity dermatitis in dogs and accounts for 8% to 10% of canine skin disorders. In atopic dermatitis, T lymphocytes and cytokines interact to initiate lesions. For example, T-helper type 2 (T<sub>H</sub>2) lymphocytes produce IL-4 and express IL-1 receptors. IL-4 enhances T-lymphocyte and mast cell multiplication. IL-3 is synergistic, particularly in the facilitation of mast cell differentiation and development. IL-4 also stimulates B lymphocytes to switch production from IgM to IgE. IgE activates mast cells. IL-1, produced by keratinocytes, is required for proliferation of T<sub>H</sub>2 cells. It is known that *Staphylococcus aureus* in human skin can enhance keratinocyte production of enough IL-1 to allow T<sub>H</sub>2 cells to become activated and initiate the lesions of atopic dermatitis. Clinical observations in dogs suggest that cutaneous infections with staphylococci and *Malassezia* yeast may play a similar role; however, definitive studies establishing such a role are lacking. In dogs, IgE is the most important antibody contributing to atopic dermatitis. Although an IgG response often accompanies an IgE response, there is little evidence to support the role of IgG in the pathogenesis of canine atopic dermatitis.

1208

The predominant clinical sign of atopy is pruritus and, in dogs, is often manifested as face rubbing and foot licking. Clinical signs of feline atopy vary and include those associated with facial, pinna, or generalized pruritus, miliary dermatitis, eosinophilic granuloma complex, and symmetric alopecia. Horses can have pruritus of the head, pinnae, ventrum, legs, and tail head, or recurrent urticaria. Primary clinical lesions are rare, and most lesions are the result of self-inflicted trauma such as excoriations, erythema, and alopecia. More chronic lesions include lichenification and hyperpigmentation. Microscopic lesions collected from nontraumatized skin in atopic dermatitis consist of superficial perivascular accumulations of lymphocytes, mast cells, variable numbers of eosinophils, and cells with a histiocytic morphologic appearance. Immunohistochemistry of atopic dog skin has revealed that the lymphocytes are T cells and the cells with the histiocytic appearance are dendritic antigen-presenting cells. Some animals, particularly horses, have deep perivascular inflammation as well. Eosinophils are seen less frequently in dogs than other species, but are the predominant inflammatory cell in horses and cats, which can also develop eosinophilic folliculitis. The epidermis in atopic dermatitis is hyperplastic and there sometimes is epidermal intercellular edema (spongiosis) that progresses to small foci of parakeratosis. In dogs, epitheliotropic mononuclear cells identified as T lymphocytes and Langerhans' antigen-presenting cells are present. Uncommonly, intraepidermal eosinophils and subcorneal eosinophil microabscesses have been observed in dogs. Lesions of self-trauma such as excoriations and secondary pyoderma consisting of epidermal and follicular pustules, with the accompanying perivascular inflammation and exocytosis of neutrophils into the epidermis, can mask mild lesions of atopic dermatitis. Diagnosis of atopy is based on clinical signs, physical examination, intradermal skin testing, and the use of the radioallergosorbent test (RAST) and the ELISA for elevated allergen-specific IgE.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.4.2.3 Insect Bite Hypersensitivity

#### 17.2.4.2.3.1 Flea bite hypersensitivity

Flea bite hypersensitivity is the most common hypersensitivity dermatitis in dogs and cats. It is mediated by type I and type IV reactions, including cutaneous basophil hypersensitivity. Flea bite hypersensitivity is pruritic. In dogs, cutaneous lesions occur principally along the dorsal lumbosacral area (Fig. 17-59), ventral abdomen, caudomedial aspects of the thighs, and flanks. In cats, lesions occur around the neck, but can be generalized, especially in highly sensitive animals. Secondary lesions are due to self-inflicted trauma. Grossly, there is a papular dermatitis with secondary excoriations. Chronic lesions include lichenification (Table 17-5), and some dogs develop multiple firm alopecic nodules (fibropruritic nodules) in the dorsal lumbosacral area. Microscopically, flea bite hypersensitivity in dogs consists of superficial perivascular dermal accumulations of mast cells, basophils, eosinophils, lymphocytes, and histiocytes. Occasionally seen are small foci of epidermal necrosis and eosinophils, called “nibbles,” which strongly suggest flea bite hypersensitivity. Fibropruritic nodules consist of a core of coarse thick collagen bundles covered by a hyperplastic epidermis; the end result of chronic inflammation associated with flea bites. In cats, the inflammatory lesions are in the superficial and deep perivascular dermis, and eosinophilic folliculitis and furunculosis also can be a feature. The overlying epidermis is acanthotic.

#### 17.2.4.2.3.2 *Culicoides* hypersensitivity

*Culicoides* hypersensitivity in horses is a common worldwide pruritic dermatitis in horses, caused principally by type I and type IV hypersensitivity reactions to salivary antigens from bites of *Culicoides* sp. Signs can be seasonal or nonseasonal depending on climate, and thus the prevalence, of *Culicoides*. Signs usually develop in horses more than 2 years of age, and in the geographic areas in which *Culicoides* live. Gross lesions depend on the stage of disease and severity of pruritus. Initial lesions are papules. Later developing lesions are pustules and nodules. Self-trauma can cause excoriations, erosions and sometimes ulcers, crusts, alopecia, and lichenification. Common sites are the tail base, withers, and head. Microscopic lesions include superficial and usually deep perivascular dermatitis with numerous eosinophils. Some horses also have eosinophilic folliculitis, intraepidermal pustules, crusts, erosions or ulcers, and eosinophilic granulomas. Older lesions have epidermal hyperplasia, hyperkeratosis, cellular crusts, and dermal fibrosis, usually the result of ulceration or folliculitis and furunculosis.

#### 17.2.4.2.3.3 Mosquito bite hypersensitivity in cats

Mosquito bite hypersensitivity develops in cats hypersensitive to mosquito antigens, presumably present within the injected mosquito saliva. Experimental studies using intradermal skin tests and Prausnitz-Kustner tests in cats indicate that these lesions are initiated by a type I hypersensitivity reaction. Mosquito bite hypersensitivity develops primarily on the external nose, but lesions can involve nasal planum, periocular skin, pinnae, and less commonly, the footpads. Lesions begin as erythematous papules, and progress to crusts, erosions, ulcers, and alopecia (Fig. 17-63). Inactive lesions can be hypopigmented or hyperpigmented, presumably from damage to or regenerative hyperplasia of melanin-containing cells in the epidermis. Histologic lesions include extensive superficial and deep, perivascular and interstitial eosinophilic to mixed dermatitis, occasionally with

1209

1210

## Pathologic Basis of Veterinary Disease, 4th Edition

foci of degranulated eosinophils (flame figures) and eosinophilic folliculitis and furunculosis. The epidermis is acanthotic with foci of erosion, ulceration, and cellular crusting (Fig. 17-63).

**Fig. 17-63 Resolving mosquito bite hypersensitivity dermatitis, skin, face, cat.** **A**, Alopecia, erythema, and erosions are present. Note the mosquito that is biting the skin. The two red depressions nearest the mosquito are healing biopsy sites collected previously during a more active stage of the disease. Mosquitoes have been kept away from this cat for one week, allowing the active lesions of hemorrhagic crusting to resolve. **B**, The dermis under the ulcer is heavily infiltrated with eosinophils, lymphocytes, and plasma cells. H&E stain. (**A**, Courtesy of Dr. Kenneth V. Mason, Animal Allergy and Dermatology Service, Springwood, Queensland, Australia. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.2.4.2.4

### Allergic Contact Dermatitis

Allergic contact dermatitis, an example of a type IV hypersensitivity reaction, is due primarily to contact with chemicals such as aniline dyes in carpets, plant resins, chemicals in shampoo, and historically to plastics in food dishes. These chemical substances contain low molecular weight haptens that require binding to cell-associated proteins before they are recognized by cytotoxic T lymphocytes ( $CD8^+$ ). Lesions develop upon reexposure to the antigen. The lesions are pruritic, result in self-inflicted trauma, vary in severity, and are located in regions in contact with the antigen, typically in areas of glabrous (smooth and bare or hairless) skin unless the antigen is a liquid or aerosol. Grossly, lesions consist of erythema, papules with or without vesicles, and exudates that develop into crusts. Chronic lesions consist of lichenification, hyperpigmentation, and alopecia. Early microscopic lesions are spongiotic superficial perivascular dermatitis with lymphocytes, macrophages, and, usually, infrequent eosinophils. However,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

some lesions have many perivascular eosinophils and eosinophilic epidermal pustules. More chronic lesions, often those identified in biopsy samples, have acanthosis and foci of parakeratotic cellular crusts. Lesions associated with self-induced trauma can also be seen.

17.2.4.2.5

### Hypersensitivity Reactions to Drugs

Hypersensitivity reactions to drugs are uncommon in dogs and cats, are rare in other domestic animals, and can result from any of the four types of hypersensitivity reactions. The drugs most commonly associated with hypersensitivity reactions include penicillins and trimethoprim-potentiated sulfonamides, but many drugs can cause a hypersensitivity reaction. Gross and microscopic lesions vary greatly. Microscopic lesions have different histopathologic patterns and include perivascular dermatitis, interface dermatitis, epidermal necrosis, vasculitis, vesiculopustular dermatitis, necrotizing dermatitis, perforating folliculitis (i.e., furunculosis), or panniculitis.

17.2.4.3

### SELECTED AUTOIMMUNE REACTIONS

17.2.4.3.1

#### Reactions Characterized Grossly by Vesicles or Bullae as the Primary Lesion and Histologically by Acantholysis

Pemphigus is a group of diseases clinically characterized by transient vesicles or bullae and histologically by acantholysis ([Table 17-12](#)). This group of diseases is caused by a type II response and involves autoantibodies produced against proteins responsible for keratinocyte cell-to-cell adhesion (desmosomes). Recall that desmosomes are the sites where cells of the stratum spinosum attach to each other, and during fixation and processing for microscopic examination, the cells of the stratum spinosum contract, except for the desmosomal attachments, which provide the appearance of “spines” or intercellular bridges (see Morphology of the Skin, Epidermis). These desmosomal protein antigens are found in various stratified squamous epithelia including skin, mucocutaneous junctions, oral mucosa, esophagus, and vagina. Damage to desmosomes results in acantholysis, which leads to the formation of vesicles or bullae within varying levels of the epidermis according to the location of the target antigen. The pathogenesis of acantholysis is unknown, but the autoantibodies themselves induce acantholysis and thus are considered pathogenic. In addition, complement activation or activation of the plasminogen-plasmin system independent of complement may play a role. However, studies using plasminogen activator knockout mice suggest that this system may not be necessary for blister formation as once thought. Other mechanisms involved in acantholysis include release of keratinocyte-derived cytokines, including IL-1 and TNF- $\alpha$ . Other autoantibodies may contribute by weakening intercellular adhesion by interfering with desmosomal protein expression or preventing new production of desmosomes. The severity of clinical disease is related to the depth of the formation of the bullae. The more severe signs are caused by separations deep within the epidermis, and the more mild signs are caused by separations in the subcorneal epidermis.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-12 Immune-Mediated Dermatoses in Which Bullae Form within or below the Epidermis

Disorder	Species	Prevalence	Clinical Distribution	Target	Location of Bullae
Pemphigus foliaceus	Dog Cat Horse Goat	Common	Skin	Desmoglein 1 in human beings and about 6% of affected dogs	
Pemphigus foliaceus subtype (panepidermal pustular pemphigus)	Dog	Uncommon	Oral  Skin	Undetermined, possibly multiple antigens	
Pemphigus vulgaris	Dog Cat Horse Goat	Rare	Oral Skin	Desmoglein 3	
Paraneoplastic pemphigus	Dog	Rare	Intraepidermal Oral Skin	210 kD envoplakin 190 kD periplakin 170 kD uncharacterized	
Bullous pemphigoid	Dog Cat Horse  Pig	Rare	Mucosal epithelium and skin	BP 180 BPAG2 Type XVII collagen (NC16A domain of BPAG2)	
Epidermolysis bullosa acquisita (EBA)	Dog	One of the more common of these bullous dermatoses	Oral Skin, areas of trauma	Type VII collagen, anchoring fibrils in sublamina densa	
Linear IgA dermatosis	Dog	Rare	Oral   Skin	Extracellular portion of BPAG2 after intracellular transmembrane and NC16A domains have been removed by proteolysis; 120 kD linear IgA (LAD-1) in upper lamina lucida	
Mucous membrane pemphigoid	Dog	Rare	Oral  Skin	97 kD antigen, possibly C-terminus of BPAG2 and laminin-5 in lower lamina lucida	

## Pathologic Basis of Veterinary Disease, 4th Edition

Lupus erythematosus (systemic and cutaneous forms)	Dog	Uncommon	Oral	Many membrane and solid antigens including DNA, RNA, nucleoprotein, histone-related antigens, and in bullous SLE subtype, type VII collagen	
	Cat		Skin		
	Horse		Systemic form		

*BP*, Bullous pemphigoid; *BPAG*, bullous pemphigoid antigen; *IgA*, immunoglobulin A; *LAD-1*, leukocyte adhesion deficiency-1; *SLE*, systemic lupus erythematosus.

\* The level of bulla formation depends on subtype of lupus erythematosus and antigen targeted, typically subepidermal with basal cell degeneration. Bullous SLE subtype is similar to EBA.

17.2.4.3.1.1

### Pemphigus foliaceus

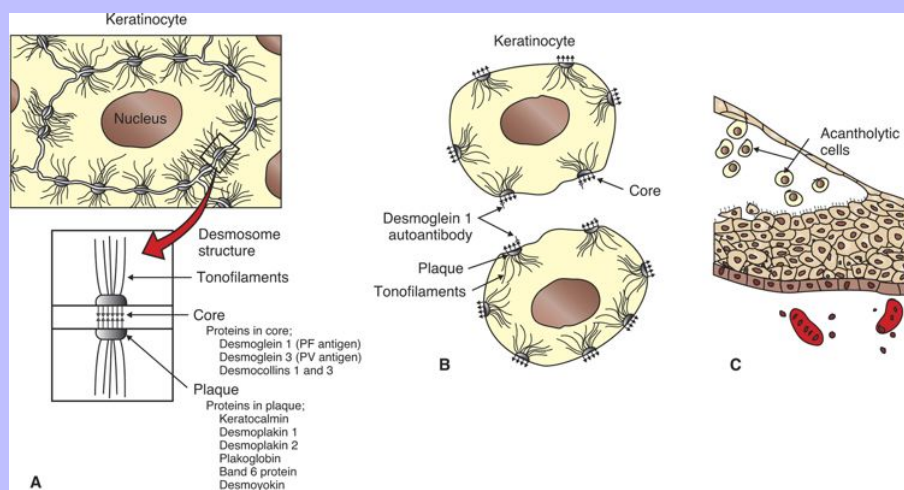

Pemphigus foliaceus (PF) is the most common and milder form of pemphigus and in domestic animals has been reported in the dog, cat, horse, and goat. The disease develops spontaneously and, in dogs and cats, as an adverse reaction to drug therapy. In human beings, PF autoantibodies recognize the desmosomal protein, desmoglein 1, which is expressed predominantly in the upper layers of the epidermis and in small amounts in the oral mucosa. Thus antibodies targeting desmoglein 1 cause cutaneous, rather than oral lesions, and the acantholytic process occurs at a superficial level in the epidermis, producing clinical lesions that are typically exfoliative (Fig. 17-64). Pemphigus foliaceus in animals is thought to be similar to that in human beings. In fact, autoantibodies to desmoglein 1 have been identified in the serum of a small percentage of dogs with pemphigus foliaceus. However, autoantibodies to other keratinocyte antigens and to the basement membrane were identified in affected dogs, indicating that canine pemphigus foliaceus is an immunologically heterogeneous disease. Autoantibodies involved in the development of pemphigus foliaceus have not been studied in cats, horses, or goats. The gross lesions are similar in all species. The primary lesions consist of transient vesicles that rapidly become pustules, which can be localized to specific areas of the skin (nose, pinnae, periocular skin, footpads, claw beds, coronary bands), or can be more generalized and symmetric. The pustules are in the superficial epidermis, covered by only a small amount of stratum corneum or a few epidermal cells. Because the pustules are fragile, they quickly rupture from minor mechanical pressure on the surface, and this leads to secondary crusts, scales, alopecia, and superficial erosions (Fig. 17-16). In the dog and cat, lesions tend to appear first on the nose, and then spread to periorbital areas, the ears, neck, and ventral abdomen. Involvement of the feet produces marked papillary hyperkeratosis and crusting of the footpads, and there is a predilection for the claw beds, occasionally leading to sloughing of claws. In cats, lesions are often seen around the nipples in addition to lesions on the face and ears. In horses, lesions often begin on the face or distal extremities, or can be localized to the coronary bands. In any species the lesions can become generalized.

1213

1214

**Fig. 17-64 Schematic diagram of the development of acantholysis in pemphigus foliaceus.** In human beings and about 6% of dogs with pemphigus foliaceus, acantholysis develops when autoantibodies bind to desmoglein 1, a glycoprotein within the extracellular core of the desmosome. **A**, Desmosomes provide physical connections between keratinocytes and consist of keratinocyte tonofilaments, an intracytoplasmic plaque region where tonofilaments insert, and an extracellular core region. Proteins in the plaque region consist of desmoplakins, plakoglobin, and others. Proteins in the core region consist of desmogleins 1 and 3 and desmocollins 1 and 3. **B**, Autoantibody attaches to desmoglein 1, which is located predominantly in desmosomes of the upper layers of the epidermis. Simple binding of the autoantibody to desmoglein 1 induces keratinocyte detachment, probably by impairing function of desmoglein 1. Keratinocyte-released cytokines or other autoantibodies may contribute by further weakening cell-to-cell attachment. **C**, An intraepidermal vesicle containing acantholytic keratinocytes is the result of loss of desmosomes between keratinocytes in the upper layers of the epidermis. *PF*, Pemphigus foliaceus; *PV*, pemphigus vulgaris. (**A**, **B**, and **C**, Adapted from Rubin E, Farber JL: Pathology, ed 3, Philadelphia, 1999, Lippincott-Raven; and Lin MS, Mascaro JM Jr, Liu Z et al: Clin Exp Immunol 107 suppl 1:9-15, 1997.)

Microscopically, acantholysis results in the formation of very transient “vesicles” (in animals the vesicle stage is not a major clinical feature as it is in human beings because the vesicle stage in animals very rapidly progresses to the pustular stage). Pustules form and progress to crusts. In the horse, subcorneal or intragranular pustules that contain the acantholytic cells are observed, but in the dog pustules often are in the stratum spinosum. Crusts should be included in the biopsy sample, especially if well-developed pustules are no longer present, as laminated crusts with acantholytic cells can help establish the histologic diagnosis. The laminated crusts are composed of multiple layers of dried pustules, one on top of the other. The dermis contains perivascular to interstitial accumulations of mixed inflammatory cells. Eosinophils are the predominant inflammatory cell in about one third of the canine and equine cases. Deposition of IgG at intercellular bridges in all layers of the suprabasilar epidermis or in the superficial epidermis demonstrated by immunofluorescence (IF) or immunohistochemistry (IHC) is a feature of PF, but is not specific for PF. With immunostaining there are frequent false negative results (poor lesion selection or prior glucocorticoid or immunosuppressive therapy) and false positive results (chronic skin lesions with plasma cells and secondary immunoglobulin diffusion into the epidermis), thus immunostaining must be interpreted carefully and in conjunction with clinical and histologic findings.

### 17.2.4.3.1.2

#### Pemphigus vulgaris

Pemphigus vulgaris (PV) is a very severe form of pemphigus and has been reported in the dog, cat, horse, and goat (Table 17-12). In the dog, autoantibodies are formed against desmoglein 3, one of the prominent desmosomal proteins involved in adhesion of basal cells of the epidermis and mucosal epithelium, thus lesions in pemphigus vulgaris, in contrast to pemphigus foliaceus, occur deeper in the epidermis and also in the oral mucosa. Microscopic lesions consist of separation of keratinocytes of the lower epidermis owing to loss of intercellular attachments. However, basal cell keratinocytes remain attached to the basement membrane, resulting in a suprabasilar vesicle leaving a row of basal cells attached to the basement membrane (“row of tombstones”) (Fig. 17-17). There usually is accompanying superficial perivascular to interface mixed inflammation. Vesicles or secondary erosions and ulcers are found in the oral mucosa, at mucocutaneous junctions, and skin subject to mechanical stress such as in the axilla or groin. Animals can be febrile, depressed, and anorectic and have leukocytosis. Drooling is often a presenting complaint, as involvement of the oral mucosa is almost always present.

### 17.2.4.3.1.3

#### Paraneoplastic pemphigus

Paraneoplastic pemphigus (PNP) is an aggressive form of pemphigus associated with solid or hematopoietic neoplasms (Table 17-12). One documented case in the dog could not be demonstrated to be associated with the presence of a neoplasm, so it is possible for this condition to occur without a concurrent malignancy. PNP has been documented in human beings and dogs. Cutaneous lesions can precede detection of the neoplastic process, and are resistant to treatment. Lesions consist of severe mucosal and mucocutaneous blistering and erosions. Histologically, lesions have a pattern of combined erythema multiforme and suprabasilar acantholysis resembling pemphigus vulgaris. One case of PNP-like disease in the horse has been documented, but in the horse there was dermoepidermal separation characteristic of bullous pemphigoid rather than pemphigus vulgaris. Lymphohistiocytic cell-rich interface dermatitis with apoptosis of keratinocytes is present. In addition, lymphocytes border apoptotic keratinocytes (this is often called “lymphocytic satellitosis”). Labeling of intercellular bridges is detected by IHC or IF. In human beings, immunoprecipitation

## Pathologic Basis of Veterinary Disease, 4th Edition

---

reveals a typical set of five protein bands with molecular weights of 250, 230, 210, 190, and 170 kD. These protein bands have been identified as desmoplakins I and II, bullous pemphigoid antigen 1, envoplakin and periplakin. In one dog, immunoprecipitation revealed the main antigen targets were 210, 190, and 170 kD.

17.2.4.3.1.4

### Pemphigus foliaceus subtypes

Pemphigus foliaceus subtypes, called “panepidermal pustular pemphigus” (PPP) by some veterinary dermatopathologists, refers to a form of pemphigus in the dog that has some of the features of PF, pemphigus vegetans, and pemphigus erythematosus. It is considered to be a subtype or variant of PF. It is similar to PF in that lesions develop in the superficial epidermis, but lesions are not restricted to the superficial layers of the epidermis and thus it does not neatly fit the same criteria as PF. Immunological studies have not definitively documented the presence of autoantibodies to desmosomal or hemidesmosomal proteins in PPP, but new studies evaluating autoantibody epidermal binding patterns in dogs with pemphigus foliaceus have identified four main IgG intercellular epidermal patterns. One of the patterns was seen in dogs with autoantibodies against desmoglein 1 (and thus is consistent with pemphigus foliaceus). Other IgG autoantibodies have been detected against intracellular keratinocyte antigens in the stratum basale, spinosum granulosum, and corneum as well as antibasement membrane antibodies. These studies suggest that superficial forms of pemphigus in the dog are heterogeneous immunologically, and these antibody-binding patterns may explain the variation in location of epidermal pustules in canine pemphigus foliaceus. Original designations of pemphigus vegetans and pemphigus erythematosus in animals were based on similarities to the human conditions. Further studies suggest the conditions are not directly comparable. Pemphigus erythematosus was considered to be a variant of PF with a facial or “lupus” lesion distribution occurring in dogs and cats. Criteria for diagnosis and differentiation from PF were dependent upon the immunological demonstration of both a diffuse cell surface IF or IHC pattern typical of the pemphigus group plus a linear band of immunoglobulin, with or without complement, deposited at the basement membrane zone. False-positive and false-negative IF and IHC results occur with such frequency that using these criteria to establish pemphigus erythematosus as a separate disease entity has come under scrutiny. Reported cases of pemphigus vegetans in veterinary patients are very limited and originally were thought to be benign variants of pemphigus vulgaris. The lack of clear clinical or histologic distinction between pemphigus vegetans and pemphigus erythematosus in the dog has led to the new inclusive entity of PPP by some veterinary dermatopathologists; however, this classification is controversial. Features used to differentiate PPP from typical cases of PF are discussed next.

1214

1215

Panepidermal pustular pemphigus is less common than PF. Akitas and Chow chows are predisposed to develop both entities. Although initially the character and distribution of gross lesions are similar and consist of erythematous macules followed by vesiculopustular lesions, over time the lesions of PPP progress to proliferative, scaly and crusted plaques or papules. Verrucous vegetations studded with small pustules are characteristic. Depigmentation of the nasal planum can develop. The predominant histologic lesions are numerous, large, intraepithelial pustules composed of eosinophils, neutrophils, and a few to large numbers of acantholytic epithelial cells that develop at various levels of the epidermis, including the subcorneal epithelium through and including the suprabasal layers. The pustules also involve the infundibular outer root sheath, and eosinophilic to neutrophilic intrafundibular mural folliculitis can be present. In mature lesions, there is papillated epidermal hyperplasia. The dermis has perivascular to interstitial mixed cellular infiltrates including eosinophils. Biopsy samples from the mucocutaneous junction or the nasal planum can be intensely plasmacytic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

with a dense band of inflammation parallel to the epidermal dermal interface. IFA or IHC may demonstrate immunoglobulin at intercellular bridges and/or the basement membrane zone; however results can be variable. Histological differentials include predominantly facial PF, bacterial pustular dermatitis, and dermatophytosis.

17.2.4.3.2

### Reactions Characterized Grossly by Vesicles or Bullae as the Primary Lesion and Histologically by Vesicles or Bullae within the Basement Membrane (Bullous Dermatoses)

Bullous dermatoses are a rare group of disorders caused by autoantibodies directed toward one or more antigens within the basement membrane zone (see Morphology of the Skin, Basement Membrane Zone; and [Table 17-12](#)), and characterized clinically and histologically by vesicles and bullae. The disorders include bullous pemphigoid (autoantibodies against bullous pemphigoid antigen 2 [BPAG2; BP180], which is type XVII collagen, a hemidesmosomal transmembrane molecule), epidermolysis bullosa acquisita (autoantibodies against type VII in the anchoring fibrils), linear IgA bullous dermatosis (autoantibodies against the 120-kD linear IgA bullous dermatosis antigen [LAD-1] in the upper lamina lucida), mucous membrane pemphigoid (autoantibodies against a 97-kD antigen in the lower lamina lucida, and laminin-5), and bullous systemic lupus erythematosus (autoantibodies against the noncollagenous amino terminus of type VII collagen) reported in one dog.

17.2.4.3.2.1

#### Bullous pemphigoid

Bullous pemphigoid (BP) is caused by autoantibodies directed against hemidesmosomal proteins. In human beings the autoantibodies are directed toward bullous pemphigoid antigen 1 (BPAG1, a 230-kD intercellular antigen) and bullous pemphigoid antigen 2 (BPAG2, also called type XVII collagen, a 180-kD hemidesmosomal transmembrane molecule). In animals, only bullous pemphigoid antigen 2 has been identified. The location and character of clinical lesions are similar to those of pemphigus vulgaris (e.g., vesicles that progress to erosions and ulcers in the oral mucosa, mucocutaneous junctional skin, and skin in the axilla or groin). Bullous pemphigoid has been reported in the dog, cat, horse, and pig ([Fig. 17-65](#)). Separation of the hemidesmosomes of the basal layer cells from the upper lamina lucida of the basement membrane leads to the microscopic lesions of vesicles and bullae. Direct immunofluorescence staining most commonly reveals IgG and complement linearly distributed at the dermoepidermal junction. Evaluation of salt-split epithelial substrates with indirect immunofluorescence reveals staining on the epithelial side of the artificial split, helping to differentiate bullous pemphigoid from epidermolysis bullosa acquisita and mucous membrane pemphigoid that are located in the sublamina densa or lower lamina lucida, respectively. The presence of eosinophils is considered to be suggestive of bullous pemphigoid. A superficial perivascular to dense band of inflammation parallel to the epidermal dermal interface can also be present, particularly if ulceration has occurred.

1215

1216

Fig. 17-65 **Bullous pemphigoid-like dermatitis, skin.** **A**, Bullous pemphigoid-like dermatitis, face, horse. Severe ulceration and hemorrhage are present in the skin, especially lateral to and above the eye, on the nose, and on the chin. Both cutaneous and mucocutaneous sites of the body lined by stratified squamous epithelium were affected. The epidermis had separated easily from the underlying dermis, leading to the formation of vesicles, bullae, and areas of ulceration (*arrows*). **B**, Subepidermal bullous dermatosis, dog. Note subepidermal vesicle formed when the intact epidermis, including the stratum basale (*arrows*) separated from the dermis (*D*). H&E stain. (**A**, Courtesy Dr. S. Terrell, College of Veterinary Medicine, University of Florida. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.2.4.3.3 Reactions Characterized Grossly by Depigmentation, Pleomorphic Papular to Macular Eruptions, or Ulceration and Histologically by Basal Cell or Keratinocyte Degeneration or Interface Inflammation

17.2.4.3.3.1 Lupus erythematosus

Systemic lupus erythematosus (SLE) is a multiorgan disease of dogs and rarely cats and horses. Factors involved in development include genetic predisposition, viral infections, hormones, and UV light. SLE is a disease of immune dysregulation, with abnormalities in both cellular and humoral immunity, including defective T-lymphocyte suppressor function and cytokine dysregulation. The defective T-lymphocyte suppression function may be due to anti-T-lymphocyte antibodies or a primary suppressor T-lymphocyte deficiency. The defective T-lymphocyte suppression function results in B-lymphocyte hyperactivity and in the formation of autoantibodies to a variety of membrane and soluble antigens, including nucleic acids. Antibodies are also directed to organ-specific antigens, clotting factors, and cells (e.g., erythrocytes, leukocytes, platelets). A bullous form of systemic lupus erythematosus caused by autoantibody directed to type VII collagen has been reported in one dog (bullous SLE). Although the autoantibodies can damage tissue, the principal mechanism of injury in SLE occurs via antigen-antibody binding (i.e., immune-complex formation), and deposition of the antigen-antibody complexes in a variety of tissues, including skin. The deposition of these immune complexes, which in the skin occurs at the basement membrane and in the walls of dermal blood vessels, results in a type III hypersensitivity response. Lesions are intensified by exposure to UV light. The enhanced damage may occur via UV-induced expression of nuclear antigens on the keratinocyte surface, autoantibody binding to the newly expressed antigens with resultant keratinocyte damage, and release of keratinocyte cytokines (e.g., IL-1, IL-6, and TNF- $\alpha$ ). Ultraviolet light may also act by inducing the expression of adhesion molecules, thus facilitating trafficking of leukocytes to the epidermis. Systemic signs are variable, but can include polyarthritis, fever, anemia, proteinuria (from glomerulonephritis), and thrombocytopenia.

1216

Cutaneous lesions are highly variable, can be localized or generalized, but commonly involve the face, pinnae, and distal extremities. Lesions consist of erythema, depigmentation, alopecia, scaling, crusting, and ulceration. Stomatitis or panniculitis can be present. Microscopic lesions include lymphohistiocytic interface dermatitis with basal cell apoptosis, pigmentary incontinence, and the presence of subepidermal vacuolization. The basal cell degeneration and subepidermal vacuolization can lead to formation of subepidermal vesicles, which can rapidly ulcerate and crust. Basement membrane thickening caused by accumulation of immune complexes, and immune-complex vasculitis of small dermal vessels can also be seen.

1217

Discoid lupus erythematosus (DLE), also called localized cutaneous lupus erythematosus and photosensitive nasal dermatitis, is seen most commonly in the dog but is rare in the cat and horse. Historically, DLE has been considered to be a mild variant of SLE in which there is no involvement of other organ systems and the antinuclear antibody titer is negative. However, with the recent recognition of another disease, “mucocutaneous pyoderma” (see Superficial Bacterial Infections [Superficial Pyodermas], Mucocutaneous Pyoderma), and the clinical and histological overlap between localized cutaneous lupus erythematosus and mucocutaneous pyoderma, the classification of DLE as a distinct entity is being revisited. Investigative studies are needed to better define these two conditions. Clinical lesions of DLE consist of depigmentation, erythema, scaling, erosion, ulceration,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

and crusting, and generally occur in the skin of the nasal planum, dorsal surface of the nose, and less commonly, the pinnae, lips, and periocular region, and in the oral mucosa. DLE can be exacerbated by sunlight. Microscopic lesions include accumulations of lymphocytes and plasma cells at the epidermal dermal interface. In early cases the infiltrate can be sparse, but in some cases the lymphocytes and plasma cells are arranged in a dense bandlike pattern that obscures the epidermal-dermal interface. In addition, there are apoptotic basal cells resulting in loss of epidermal pigment that is phagocytosed by dermal macrophages (pigmentary incontinence). As with SLE, the basal cell degeneration can, in more severe cases, lead to subepidermal vesicles, loss of the epidermis, and ulceration and crusting. Other forms of lupus erythematosus also uncommonly occur in dogs.

Exfoliative cutaneous lupus erythematosus is formerly known as lupoid dermatosis of the German shorthair pointer. Lesions develop in German shorthair pointers between 3 months and 3 years of age. Clinical lesions consist of scaling and crusting first seen on the face, ears, and back. Lesions then become generalized. The lesions persist, but wax and wane. Fever and lymphadenopathy can be present. Rarely there is a positive antinuclear antibody titer. Histologic lesions consist of lymphocytic interface dermatitis with hydropic degeneration of basal cells and apoptosis of keratinocytes. Interface inflammation also affects the basilar epithelium of follicles and sebaceous glands, resulting in sebaceous gland atrophy.

Vesicular cutaneous lupus erythematosus is a disorder formerly known as ulcerative dermatosis of the collie and Shetland sheepdog. Lesions develop in middle age to older dogs. The Shetland sheepdog and collie appear predisposed to lesion development. Clinical lesions develop in the groin and axillary areas and consist of vesicles and bullae that progress to ulcers. Lesions can be cyclic, and worsen in association with estrus. Histologic lesions include interface lymphocytic dermatitis with hydropic degeneration of basal cells, keratinocyte apoptosis, and extensive vesicles and bullae at the epidermal-dermal junction that progress to ulcers.

Lupus panniculitis is a rare manifestation of lupus erythematosus, and is seen in dogs. Clinical lesions consist of nodules occurring predominantly in the subcutis of the trunk and proximal aspects of the legs. Histologic lesions consist of nodular masses of lymphoplasmacytic and histiocytic inflammation often with fat necrosis. Vasculitis can also be present. In addition, there may be apoptotic basal cell degeneration, pigmentary incontinence, and thickening of the basement membrane.

### 17.2.4.3.3.2

#### Erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN)

These are uncommon to rare diseases affecting the skin and sometimes mucous membranes. The conditions can be the result of adverse drug reactions, secondary to systemic or localized infections or neoplasia, or may be idiopathic. There is considerable overlap in both gross and histological lesions among EM, SJS, and TEN, with clinical forms varying from mild to very severe. Future in-depth studies of these cases scrutinizing the character and extent of clinical and histological lesions in correlation with the clinical history may help determine the likelihood of drug causation. In human beings, studies of this nature have indicated that drugs are the more likely cause in patients with more severe lesions of the epidermis (SJS, TEN), whereas patients with less severe lesions (EM) were more likely to be associated with an underlying infection, particularly with herpesvirus. Results of these studies in animals are not yet available.

1217

EM has been seen in dogs, cats, horses, and cattle and is characterized clinically initially by circular areas of erythema. The erythema disappears from the center of the lesions, producing targetlike lesions that are most common on the trunk and groin. Papules, vesicles, ulcers, erosions, and serpiginous erythematous lesions also can be seen (Fig. 17-13). Histologically, individual keratinocytes in all layers of the epidermis undergo apoptosis (Fig. 17-13) and are surrounded by lymphocytes (lymphocytic satellitosis). Apoptotic keratinocytes can coalesce, leading to the clinically visible erosions and possibly ulcers. Hydropic lymphocytic interface dermatitis of varying severity is also present. Mucous membranes can be involved in the more severe forms of EM (EM major), and some refer to the more severe form of EM as the Stevens-Johnson syndrome. The condition can be self-limiting. Graft-versus-host disease, seen after bone marrow transplantation, is similar histologically to erythema multiforme. TEN is seen principally in dogs and cats, is a more serious condition than EM, and may overlap in the spectrum of gross and histological lesions with the more severe forms of EM and with the SJS. TEN is a life-threatening, severe ulcerative disorder of the skin and oral mucous membranes that begins clinically as widespread erythematous macules that coalesce. Later there is full-thickness epidermal necrosis that results in large subepidermal bullae and widespread ulceration as the necrotic epidermis is sloughed. Lesions are often present on the face, mucocutaneous junctions, and footpads, but can be more widespread. Histologically there is full-thickness coagulative necrosis of the epidermis, with separation of the epidermis from the dermis forming bullae, which detach and leave the dermis denuded. Dermal inflammation in the acute lesions is minimal.

17.2.4.3.3

## Uveodermatologic syndrome (Vogt-Koyanagi-Harada-like [VKH] syndrome)

This is a rare syndrome of histiocytic interface dermatitis and granulomatous uveitis in dogs, particularly akitas, Chow chows, samoyeds, and Siberian huskies. The pathogenesis is thought to involve an immune-mediated attack against melanin or melanocytes. Ocular lesions usually develop before cutaneous lesions. Clinical lesions consist of symmetrical patchy to diffuse depigmentation of the skin of the nose, lips, eyelids, and footpads. Lesions are occasionally more widespread. Leukotrichia of adjacent hair can be present. Uncommonly lesions are more severe, and consist of erosion, ulceration, and crusting. Fully developed histologic lesions are cell-rich interface inflammation, primarily of histiocytic cells containing melanin pigment (pigmentary incontinence). Basal cell degeneration is uncommon.

17.2.4.3.4

## Reactions Characterized Grossly by Hemorrhage, Edema, Necrosis, Ulceration, Infarction, or by Alopecia and Scarring and Histologically by Vasculitis or Thrombosis

In human medicine, two principal mechanisms are thought to contribute to the pathogenesis of vasculitis; these include direct invasion of vessels by infectious agents (e.g., *Rickettsia*, herpesvirus) and immune-mediated mechanisms (immune-complex formation, antineutrophil cytoplasmic antibodies, and antiendothelial cell antibodies). This is likely true for vasculitis in animals. Evidence for the role of immune-complex deposition is derived from experimental studies (Arthus phenomenon and serum sickness), and from identification of immune complexes in serum and tissues in patients with vasculitis caused by infectious agents and hypersensitivity reactions to drugs. Thus infectious agents can contribute to immune complex-mediated vasculitis. The immune complexes can form in the circulation, in the vessel wall, or both. The role for antineutrophil cytoplasmic antibodies in causing cutaneous vasculitis is

## Pathologic Basis of Veterinary Disease, 4th Edition

---

less clear. Although these antibodies are present in the serum of patients with vasculitis, there is no proof that these antibodies actually play a causative role. It is thought that the antibodies form after an initial stimulus, such as an infection, which causes release of proinflammatory cytokines (TNF) and microbial products (endotoxin). These inflammatory mediators can cause neutrophils to express surface receptors (i.e., proteinase-3 and myeloperoxidase) against which the antibodies develop. It is theorized that the binding of the antibodies to receptors on activated neutrophils causes neutrophil degranulation and damage to tissue, including damage to endothelial cells. Resultant endothelial-cell damage potentially could cause release of “non-self” antigens and stimulation of additional antibody or cell-mediated immune responses, further perpetuating vascular injury.

17.2.4.3.4.1

### Dermatomyositis and similar disorders with cutaneous and vascular lesions

Dermatomyositis is an inherited disease with variable expressivity that occurs in juvenile and adult onset forms in collies and Shetland sheepdogs (Fig. 17-66). Other breeds are occasionally affected. The pathogenesis involves vasculitis of skin, muscle, and sometimes other tissues. The vascular lesions are subtle and include mild thickening of the vessel wall, occasionally pyknotic cells in the vessel wall, and occasionally lymphocytes within the wall; these changes are termed “cell-poor” vasculitis. Circulating immune complexes have been identified, and likely play a role.

Dermatomyositis develops in puppies as early as 8 weeks of age. Early lesions include vesicular dermatitis of face, lips, and external ears, which progresses to involve the distal extremities, especially over bony prominences and the tip of the tail. Myositis and atrophy of muscles of mastication, distal extremities, and, sometimes, esophagus develop after the dermatitis (Fig. 17-66). The myositis is variably severe and multifocal, but more prevalent in peripheral anatomic locations. The muscle inflammation consists of lymphocytes, plasma cells, histiocytes, and fewer neutrophils or eosinophils. Perifascicular myofiber atrophy (atrophy at the periphery of muscle fascicles) occurs occasionally. The rostral and most superficial portion of the temporalis muscle is the biopsy site of choice to confirm the myositis. Dermatomyositis varies in severity. Mild skin lesions heal without scarring, but moderate skin lesions heal with permanent foci of alopecia, hyperpigmentation, and scarring. Hypopigmentation can also develop from damage to melanin-containing cells in the basal layer of the epidermis. Skin and muscle lesions in dogs with severe disease are progressive and disfiguring, the result of severe scarring of the skin and atrophy of muscle. Microscopic skin lesions include interface dermatitis with basal cell degeneration of the epidermis and follicular wall, variable epidermal vesicles and pustules, follicular atrophy, and dermal scarring. Cell-poor vasculitis, a major feature contributing to the lesions in dermatomyositis, is not always identified in small biopsy samples. The combination of interface dermatitis and mural folliculitis with follicular atrophy and cell-poor vasculitis has been considered to represent ischemic lesions, and is referred to as “ischemic dermatopathy.”

1218

1219

Fig. 17-66 **Dermatomyositis, skin, dog.** **A**, Face. Chronic lesions of hair loss, hyperpigmentation, and scarring are present in the skin around the eye and on the lateral side of the face. Interface dermatitis, myositis, and vasculitis have resulted in ischemic follicular atrophy, muscle atrophy, and scarring. The scarring and possibly also some muscle atrophy have contributed to the contraction of the skin of the eyelid and the inability to close the eyelids fully at the medial canthus (*arrows*). **B**, Lip. Erosion is present on the surface of the lip skin at the far right. Atrophy of the dermis and adnexa, present here, can predispose to injury of the epidermis and superficial dermis by minor trauma. Muscle atrophy (*arrows*) and scarring around the muscle fibers are present. If muscle is present in skin biopsy samples with features of dermatomyositis, and if muscle atrophy or myositis are seen, the diagnosis of dermatomyositis is strengthened. H&E stain. (**A and B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Skin and vessel lesions indistinguishable from those in dermatomyositis occur in multifocal rabies vaccine-induced dermatitis in dogs and in the syndrome of cutaneous vasculitis in Jack Russell terriers. In some of the Jack Russell terriers, cutaneous and vascular lesions develop 2 to 3 weeks after

## Pathologic Basis of Veterinary Disease, 4th Edition

---

vaccination. Rabies vaccine-induced dermatitis develops as a localized form limited to the site of vaccination and as a more widespread form, both developing in the months following rabies vaccination. In the localized form, rabies antigen has been detected in follicular epithelial cells and in vessels in affected skin. In the widespread form, lesions are present at the site of vaccination, ear margins, periocular skin, and skin over bony prominences, tip of tail, and paw pads. Lingual erosions and ulcers also occur. In addition, some dogs develop perifascicular muscle atrophy and perimysial fibrosis, with C5b-9 in the microvasculature. The development of lesions after vaccination and the identification of rabies-virus antigen in the vessels and follicular epithelial cells in dogs with the localized form of rabies vaccine-induced dermatitis has resulted in the speculation that lesions might be a result of an immunological reaction to viral antigen in these sites in genetically predisposed dogs.

1219

Familial vasculopathy of German shepherd dogs appears to have a genetic basis, but the underlying cause and pathogenesis are unknown. Cutaneous and vascular lesions have similarities to ischemic dermatopathy. Puppies, about 1 to 2 months of age are affected, and some puppies develop lesions after vaccination. The major clinical lesion is swelling of footpads, and some puppies develop ulcers on the footpads, ear margins, and tail tip, and nasal planum with depigmentation of the nasal planum or nasal commissures. Histologically, early vessel lesions include neutrophil infiltration of small venules and arterioles, but more commonly vascular lesions are subtle and consist of cell-poor vasculitis (mild thickening of the vessel wall with occasional pyknotic cells and lymphocytes within the wall). In addition, cutaneous lesions consist of mild interface dermatitis with pigmentary incontinence. The nodular lesions in footpads are in the dermis and subcutis, and early lesions consist of focal collagen degeneration bordered by neutrophils and mononuclear cells. Chronic lesions have dermal and subcutaneous fibrosis sometimes accompanied by degeneration and fibrosis of skeletal muscle bundles.

1220

17.2.4.3.4.2

### Cutaneous and renal glomerular vasculopathy of the greyhound

Greyhounds with this condition are typically from race track environments. The cause and pathogenesis are unknown; however, there is speculation that the disorder is similar to hemolytic-uremic syndrome in human beings where a verotoxin (Shiga-like toxin) damages vascular endothelium. Most racing greyhounds eat raw meats, which could contain the *Escherichia coli*-producing toxin. Clinical lesions include hemorrhagic macules that progress to deep ulcers of the tarsus, stifle, or inner thigh. Occasionally lesions develop on the front legs, groin, or trunk. Lesions heal slowly (usually over 1 to 2 months) by fibrosis. Histologically, capillaries, venules, and arterioles in the dermis and occasionally the subcutis have degenerate walls with pyknotic or karyorrhectic nuclei, and occasionally fibrinoid necrosis. Fibrin thrombi can result in cutaneous infarction. About 25% of the affected greyhounds also have systemic signs of renal failure because of glomerular arteriolar inflammation, necrosis, and thrombosis.

17.2.4.3.4.3

### Cold agglutinin disease

Cold agglutinin disease is an autoimmune disease that has rarely been reported in dogs and cats, and is caused by the presence of autoantibodies directed against erythrocytes. The autoantibodies are active at cool temperatures (0° to 37°C). Clinical lesions include erythema, hemorrhage, cyanosis, necrosis, and ulceration of the extremities. Histologic lesions include edema, hemorrhage, necrosis, ulceration and inflammation associated with secondary infection. Vessels with homogeneous eosinophilic material (cryoglobulin) occasionally are identified.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.4.4 DIAGNOSIS OF AUTOIMMUNE SKIN DISORDERS

The diagnosis of autoimmune disorders is based on distribution and appearance of gross and microscopic lesions. Other diagnostic tools include the demonstration of immunoglobulin (IgG, IgM, or IgA) with or without complement, via direct immunohistochemistry, in intercellular areas (pemphigus vulgaris and foliaceus), at the basement membrane (BP, SLE, DLE, and linear IgA dermatosis), or in vessels (cutaneous vasculitis), and the results of clinical immunologic tests such as antinuclear antibody titers and Coombs' test. Unfortunately, false negative and false positive results are frequent in direct immunohistochemical staining, limiting the usefulness of this procedure. Newer techniques that detect more specific antigens such as desmoglein, use of "salt-split" skin sections for subepidermal bullous diseases, and use of better substrates for indirect immunostaining improve diagnostic accuracy of immune-mediated skin diseases, but these testing procedures currently are not universally available. The "salt-split" technique uses a 1-molar solution of NaCl to split the skin through the lamina lucida. This allows identification of autoantibodies that bind to the roof (epidermal), floor (dermal), or combined sides of the split and increases accuracy of diagnosis in bullous dermatosis.

### 17.2.5 DISORDERS WITH ALOPECIA OR HYPOTRICHOSIS

Cutaneous endocrine disorders are due to imbalances in hormones and generally are manifested as nonpruritic, bilaterally symmetric alopecia or hypotrichosis (Box 17-11). The remainder of the hair coat is dull, dry, easily epilated, and fails to regrow after clipping. The epidermis is often hyperpigmented. These lesions are referred to as "endocrine alopecia." In disorders associated with alterations in sex hormones, the alopecia often begins in the perineal and genital areas and can extend cranially. However, it is not uncommon for a cutaneous endocrine disorder to have asymmetric alopecia and epidermal hyperpigmentation along with secondary pyoderma or seborrhea. Microscopically, uncomplicated endocrine disorders of the skin consist of hyperkeratosis of superficial epidermis and of hair follicles; normal, atrophic, or hyperplastic epithelium; dilated follicles from hyperkeratosis; increased numbers of catagen or telogen hair follicles; lack of hair shafts in follicles; and increased epidermal pigmentation. These general features support the diagnosis of an endocrine disease, but often are not sufficiently specific to be diagnostic for an individual endocrine disorder.

1220

1221

Also, inflammation due to secondary seborrhea or pyoderma frequently complicates the diagnosis. Selected clinical and histologic features of individual endocrine disorders (e.g., clinical evidence of cutaneous and muscle atrophy and histologic evidence of mineral deposition in the case of hyperglucocorticoidism) in conjunction with clinical testing are used to establish a more definitive diagnosis. Cutaneous endocrine disorders are more common in dogs than in cats, food animals, or horses.

### 17.2.5.2 **CUTANEOUS ENDOCRINE DISORDERS**

#### 17.2.5.2.1 **Hypothyroidism**

Deficiency of thyroid hormone is considered the most common endocrine disorder in dogs and is caused by idiopathic thyroid atrophy and lymphocytic thyroiditis. Thyroid hormones play an essential role in normal growth and development of many organs including the skin, and can result in a variety of systemic and cutaneous signs and lesions. In dogs, the hair follicle is considered to be an important target for thyroid hormones, where the hormones are thought to be necessary for the initiation of the anagen

## Pathologic Basis of Veterinary Disease, 4th Edition

---

stage of the hair cycle. Clinical lesions of thyroid deficiency consist of a dull, dry, easily epilated hair coat that fails to regrow after clipping. Alopecia of the dorsal surface of the nose is present in some hypothyroid dogs. Symmetrical truncal alopecia is also considered to be a feature of hypothyroidism, but may not be as common as once thought. Microscopically, the primary hair follicles are usually in the telogen stage of the hair cycle, and the old primary hair shafts are retained in follicular lumens. There are increased numbers of secondary hair follicles in the telogen stage of the cycle, but these follicles generally have lost the old secondary hair shafts. Follicular infundibular hyperkeratosis with plugging of the follicular opening is also present. Other histologic changes attributed to hypothyroidism include acanthosis of epidermis and follicular infundibular epithelium, an increase in dermal mucin (myxedema), which results in dermal thickening, and vacuolated or hypertrophic arrector pili muscles. Secondary staphylococcal infection can develop.

Hypothyroidism can also be the result of congenital iodine deficiency. Iodine deficiency develops in fetuses because of maternal ingestion of diets deficient in iodine or containing substances that interfere with production of thyroid hormones (goitrogens). These factors result in insufficient synthesis of thyroxine and reduced blood levels of thyroxine and triiodothyronine. The reduced levels of these hormones are detected by the hypothalamus and pituitary gland, stimulating secretion of thyrotropin and resulting in hyperplasia of the thyroid follicular cells. Regions of North America that are deficient in iodine include the Great Lakes Basin, the Rocky Mountains, the Northern Great Plains, the upper Mississippi Valley, and the Pacific Coast region. Paradoxically, maternal diets high in iodine can also result in congenital hypothyroidism. High blood iodine also interferes with one or more steps of thyroid hormone production, leading to low blood thyroxine levels, hypothalamic and pituitary stimulation, and secretion of thyrotropin. Congenital iodine deficiency can occur in any domestic animal but usually is seen in large animals; it is associated with the birth of dead fetuses or weak neonates. These neonates can have alopecia, and thyroid glands are usually enlarged because of the follicular cell hyperplasia.

1221

### 17.2.5.2.2

#### Hyperadrenocorticism

1222

Hyperadrenocorticism results in cutaneous lesions principally in dogs and cats, and is usually caused by bilateral adrenal cortical hyperplasia secondary to a pituitary neoplasm, a functional adrenal cortical neoplasm, a functional nodule of cortical hyperplasia, or the administration of exogenous glucocorticoids. In dogs, cutaneous lesions include endocrine alopecia that generally spares the head and extremities, thinning of the skin, comedones, increased bruising, poor wound healing, and increased susceptibility to infection (Fig. 17-67). Dystrophic calcification of the dermis of the back, inguinal, and axillary areas can occur in dogs, particularly in iatrogenic hyperadrenocorticism (calcinosis cutis) (Fig. 17-68). Grossly, lesions of calcinosis cutis are firm, thickened, sometimes gritty, often ulcerated and alopecic, crusted plaques or nodules (Fig. 17-68). In cats, the dermal collagen fibers can be markedly thin and atrophic, resulting in extremely fragile skin that can tear with normal handling. Microscopically, the lesions of hyperadrenocorticism include epidermal, dermal, and follicular atrophy (Fig. 17-67), follicular hyperkeratosis, and calcinosis cutis, especially in dogs (Fig. 17-68). A foreign body reaction (granulomatous inflammation) and draining sinuses can develop in association with the calcium deposits.

1222

1223

Fig. 17-67 **Truncal alopecia, hyperadrenocorticism, skin, dog.** **A**, Note the alopecia, distended abdomen, and thin skin in which blood vessels are faintly visible (*arrow*). The distended abdomen and visibility of blood vessels are a result of protein catabolism and loss of muscle and dermal collagen, respectively. The distended abdomen and thin skin with greater visibility of blood vessels in conjunction with symmetrical alopecia suggest that a catabolic endocrine disease such as hyperadrenocorticism is likely. **B**, Atrophy of dermal collagen fibers is so severe that the collagen has almost disappeared, leaving the adnexa and arrector pili muscles readily visible. Hair follicles are in the telogen (resting) stage of the hair cycle. H&E stain. (**A**, Courtesy Dr. Allan Mundell, Animal Dermatology Service. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Fig. 17-68 **Calcinosis cutis, hyperadrenocorticism, skin, dog.** **A**, Dorsal neck. The skin is partially alopecic, ulcerated, and crusted. It is also palpably thickened. **B**, Subcutis. Mineral deposits are visible as white nodular foci. **C**, Skin at the margin of a plaque is thickened by dermal mineralization and granulomatous inflammation (*left half*). H&E stain. **D**, Higher magnification of dermal mineralization (*arrows*) and granulomatous inflammation. H&E stain. (**A**, Courtesy Dr. Allan Mundell, Animal Dermatology Service. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C** and **D**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

17.2.5.2.3

### Hyperestrogenism

Hyperestrogenism can develop in male and female dogs. In females, the estrogen originates from ovarian cysts, rarely an ovarian neoplasm, or from estrogen administration. In males, elevated serum concentrations of estrogen are usually derived from a functional testicular Sertoli cell tumor. Iatrogenic estrogen administration has also caused hyperestrogenism in male dogs (Fig. 17-69). In addition to endocrine alopecia, female dogs have an enlarged vulva and abnormalities of the estrus cycle. Male dogs can develop gynecomastia, pendulous prepuce, or an enlarged prostate because of squamous metaplasia of prostatic ducts. Cutaneous microscopic lesions include orthokeratotic hyperkeratosis, follicular hyperkeratosis, and telogen follicles (Fig. 17-69).

17.2.5.2.4

### Alopecia X of Nordic Breeds (Adrenal Sex Hormone Alopecia, Castration Responsive Dermatitis, Growth Hormone Responsive Dermatitis)

This condition is seen most often in Nordic breeds of dogs (e.g., Pomeranian, Chow chow, Samoyed, Keeshond, Siberian husky, Alaskan malamute, Norwegian elkhound, Finnish spitz, American Eskimo). Poodles, and sporadically other breeds of dogs, are also affected. Dogs with this condition (or conditions) are grouped together by having in common (1) plush hair coats in the normal state (e.g., when not affected with this condition), (2) alopecia sparing head and distal extremities, (3) normal thyroid and glucocorticoid levels, and (4) skin biopsy samples with telogen follicles and often prominent flame follicles (follicles with prominent tricholemmal keratin that forms spikes into the follicular stratum spinosum). The alopecia often develops at 1 or 2 years of age in otherwise healthy dogs of either sex. The alopecia is symmetric and involves the perineum, caudal thighs, ventral abdomen and thorax, neck, and trunk. The head and distal extremities are spared. Hyperpigmentation is usually present (Fig. 17-70). Thyroid function testing, ACTH (adrenocorticotrophic hormone) response test, low-dose dexamethasone suppression test, and serum chemistry results are normal. Abnormalities in a number of hormones have been detected, but most work has involved the evaluation of 21-hydroxylase enzyme and other adrenocortical enzymes necessary for adrenal steroidogenesis. In the Pomeranian dog, partial deficiency of 21-hydroxylase enzyme has been detected and results in dysregulation of adrenal hormone synthesis, decreased cortisol levels, and in hyperprogestinism and hyperandrogenism (similar to late-onset, nonclassic congenital adrenal hyperplasia in human beings). Castration provides a temporary response to the alopecia by eliminating the influence of testicular hormones. Microscopic lesions include follicular inactivity (telogen-stage follicles without hair shafts) and prominent formation of flame follicles (Fig. 17-70, B). Prominent diffuse flame follicle formation is suggestive of alopecia X, but flame follicles can be seen normally, especially in some breeds (Shar-Pei dogs), in other endocrine dermatoses (hyperestrogenism and hyperadrenocorticism, particularly in plush-coated breeds), and in follicular dysplasia of the Siberian husky. Follicles similar to flame follicles but with less exaggerated tricholemmal keratin spikes and with hair shafts retained are seen in normal plush-coated breeds of dogs and in post clipping alopecia. Epidermal hyperpigmentation and dermal atrophy are variable.

1223

1224

Fig. 17-69 **Symmetrical alopecia and hyperpigmentation, hyperestrogenism (iatrogenic from diethylstilbestrol therapy), skin, dog.** **A**, Note the symmetrical alopecia and hyperpigmentation over the caudal dorsal trunk and caudolateral hind legs. In male dogs, the symmetrical alopecia in conjunction with enlargement of nipples, pendulous prepuce, and attraction of other male dogs suggest the possibility of hyperestrogenism. **B**, Note epidermal orthokeratotic hyperkeratosis (*arrowhead*), follicles dilated with keratin (*F*), and small atrophic follicles (*arrows*) in the telogen (resting) stage of the hair cycle. H&E stain. (**A and B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

Fig. 17-70 **Alopecia X, skin, dog.** **A**, “Alopecia X of Nordic breeds,” Chow chow. Note the partial alopecia and hyperpigmentation of trunk. The alopecia is not diagnostic for a specific condition. The breed suggests that alopecia X of Nordic breeds should be considered as one of the differential diagnoses. **B**, Flame follicle, haired skin. The hair follicle has excessive trichilemmal keratinization resembling the spikes (*arrows*) of a flame and consistent with a “flame follicle.” H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.5.2.5 Hypersomatotropism

This syndrome rarely occurs in adult dogs, and is a result of excess levels of growth hormone (somatotropin). The excess growth hormone can arise from acidophil tumors of the anterior pituitary gland, injection of pituitary gland extracts, administration of progestins, or with the metestrus (luteal) phase of the estrous cycle in intact female dogs. Hypersecretion of growth hormone results in increased production of connective tissue, bone, and viscera. Clinical lesions consist of acromegaly (enlargement of parts of the skeleton, especially distal extremities), and thick, folded myxedematous skin over the head, neck, and extremities. The hair coat can be long and thick, and the claws thick and hard. Histologic lesions include thickened dermis caused by increased production of glycosaminoglycans and collagen by dermal fibroblasts. Myxedema is present in about a third of cases.

### 17.2.5.2.6 Hyposomatotropism

Deficiency of growth hormone in dogs younger than 3 months of age is usually due to failure of the normal development of the pituitary gland leading to cyst formation. Deficiencies of thyroid, adrenal, and gonadal hormones are frequent accompanying problems. Pituitary deficiency results in failure to grow, retention of the puppy hair coat, and development of endocrine alopecia. Microscopically, the features are consistent with endocrine alopecia (e.g., hyperkeratosis of superficial epidermis and of hair follicles; normal or atrophic epithelium; follicular dilation from hyperkeratosis; increased numbers of telogen hair follicles; lack of hair shafts in follicles; and increased epidermal pigmentation). The numbers of dermal elastic fibers are reduced in the skin of some dogs.

### 17.2.5.2.7 Cyclical Flank Alopecia (Seasonal Flank Alopecia, Idiopathic Flank Alopecia)

Cyclical flank alopecia develops more commonly in dogs living in northern latitudes. The cause of cyclical flank alopecia is not known, but changes in the photoperiod, and thus melatonin released from the pineal gland, might play a role. Many breeds are affected, but English bulldogs, boxers, and Airedale terriers are among the more commonly affected breeds. Alopecia develops seasonally or cyclically in the skin of the flank, usually bilaterally (Fig. 17-71). Histologically, follicles are in the telogen stage of the hair cycle, and primary follicles are markedly dilated and distorted by follicular hyperkeratosis. The follicular hyperkeratosis also distends the openings of secondary follicles as they enter the primary follicle, giving the follicles the distorted appearance of an upside-down “footprint” (Fig. 17-71, B). The condition, as the name suggests, is often transient but can be recurrent.

1224

1225

Fig. 17-71 **Cyclical flank alopecia (seasonal flank alopecia), skin, dog.**

**A**, Alopecia and hyperpigmentation are present in the skin of the flank of a boxer dog. The breed of dog, location of the alopecia, and often cyclic nature of the condition suggest that cyclical flank alopecia is a likely diagnosis. Hair is regrowing in the central area of alopecia (*brown area within hyperpigmented zone*), indicating that lesions are resolving. **B**, Note the distorted follicle with dilations at the base. The follicle resembles an upside-down “footprint.” This histologic feature, in conjunction with clinical history of cyclical flank lesions in the predisposed breeds, supports the diagnosis of this condition. H&E stain. (**A**, Courtesy Dr. David Duclos, Animal Skin and Allergy Clinic. **B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.5.3 CUTANEOUS NON-ENDOCRINE DISORDERS ASSOCIATED WITH HAIR CYCLE ABNORMALITIES

#### 17.2.5.3.1 Post Clipping Alopecia

Post clipping alopecia is a failure of the hair to regrow in apparently normal dogs after close clipping. The condition usually occurs in long-haired or heavily coated (plush-coated) breeds of dogs such as the Chow chow. The cause is not known. It has been speculated that close clipping could cause a change in thermoregulation that may stimulate active follicles to simultaneously enter the telogen (resting) stage of the hair cycle. Alternatively, it is thought that heavily coated breeds of dogs have a prolonged telogen stage of the hair cycle, possibly to conserve energy by avoiding frequent cycles of shedding. Thus clipping when the hair coat is in a prolonged inactive stage of the hair cycle would result in lack of quick regrowth of the hair coat. The hair coat may not regrow until there is another significant growth phase, which may take 6 to 12 months. Most affected dogs regrow hair coat after they go through a cycle of heavy shedding. Histologic lesions consist of normal epidermis, dermis, and sebaceous glands, and hair follicles in the telogen stage of the hair cycle with prominent tricholemmal keratin resembling flame follicles but in which the hair shafts are retained.

#### 17.2.5.3.2 Telogen Effluvium

Telogen effluvium develops when an animal is systemically ill or is severely stressed such as occurs with high fever, pregnancy and lactation, or anesthesia and surgery. The illness or stressful event triggers a sudden termination of the growth stage of follicles. This causes a majority of the hair follicles to synchronously enter the catagen and then telogen stages of the hair cycle. Gross lesions do not develop until about 1 to 3 months after the systemic illness or stress resolves, and the telogen (or inactive) follicles synchronously enter into the anagen stage of the hair cycle. When the new anagen hair shafts emerge from the follicle, the old telogen hair shafts are suddenly shed. The alopecia resolves as the new hair shafts emerge from the follicles, and the new hair coat becomes visible. Histologic lesions during the stage of excessive shedding are essentially normal and consist of the majority of follicles in the anagen stage of the hair cycle.

#### 17.2.5.3.3 Anagen Defluxion

Anagen defluxion occurs when there is an insult to the anagen (or growing) hair bulbs. This most commonly occurs in dogs with continuously growing hair coats such as poodles, when given antimitotic drugs that damage the hair matrix cells (keratinocytes) of the anagen hair bulb. Gross lesions consist of alopecia that develops suddenly after the administration of the antimitotic drug. Histologic lesions can be subtle and include degeneration and fragmentation of nuclei in the keratinocytes of the hair matrix of the anagen hair bulbs, and eosinophilic hair shafts within the follicular canal.

1225

### 17.2.5.4 DISORDERS ASSOCIATED WITH NORMAL FOLLICLES

1226

Excessive grooming, particularly in cats, can result in symmetrical alopecia or hypotrichosis that clinically resembles endocrine dermatoses. Excessive grooming can be the result of pruritus (usually associated with cutaneous hypersensitivity reactions) or allegedly from psychogenic problems such as boredom or stress

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(feline psychogenic alopecia). Thus it is important to determine if the alopecia or hypotrichosis is the result of excessive grooming, and if so, what the underlying stimulus is.

### 17.2.5.4.1 Feline Psychogenic Alopecia

Psychogenic alopecia occurs in cats of the more emotional breeds, including Siamese and Abyssinian, and possibly others. A partial alopecia is due to the breaking of hairs from gentle, but persistent, licking. Linear or symmetric areas of alopecia are found along the caudal dorsal midline or in the perineal, genital, caudomedial thigh, or abdominal areas. Microscopically, the skin is generally normal, but the number of telogen follicles is increased. The principal differential diagnosis is alopecia due to hypersensitivity (see next discussion). Endocrine associated alopecia is rare in the cat.

### 17.2.5.4.2 Alopecia Due to Hypersensitivity Reactions in the Cat

Clinical signs of alopecia due to hypersensitivity reactions are often identical to those of feline psychogenic alopecia. Pruritus typically is due to hypersensitivity reactions of a variety of causes (food allergy, parasitism, atopy). Histologically, there is perivascular dermatitis, usually with eosinophils, mast cells, and lymphocytes. The inflammation helps to distinguish alopecia associated with hypersensitivity from that of feline psychogenic alopecia.

### 17.2.5.5 DISORDERS ASSOCIATED WITH DYSPLASTIC FOLLICLES

#### 17.2.5.5.1 Follicular Dysplasia Syndromes

Follicular dysplasia syndromes, defined as incomplete or abnormal development of follicles and hair shafts, comprise a group of generally poorly characterized disorders recognized most commonly in dogs, but occasionally in horses, cattle, and cats. Clinical lesions are alopecia or hypotrichosis, and consequently, there is clinical resemblance to the endocrine disorders. Some of the more common follicular dysplasia syndromes are associated with coat color dilution (color dilution follicular dysplasia, color mutant alopecia) or occur in black versus white haired areas (black hair follicle dysplasia) (Fig. 17-25). Microscopic features of follicular dysplasia vary with the syndrome. The conditions associated with coat color dilution or those that occur in black-haired areas have densely clumped melanin pigment in the hair bulb, hair shafts, and also in the basal layer of the epidermis (Fig. 17-25). Lesions in other conditions include lipid distention of hair matrix cells, abnormally formed follicles or hair bulbs, and abnormal hair shafts. The microscopic features help to differentiate syndromes of follicular dysplasia from the endocrine dermatosis.

### 17.2.6 DISORDERS RELATED TO NUTRIENT IMBALANCES, DEFICIENCIES, OR ALTERED METABOLISM

#### 17.2.6.1 MALNUTRITION

Malnutrition can be primary (dietary deficiency of proteins, fats, carbohydrates, vitamins, minerals, amino acids, or fatty acids) or secondary (diet is adequate, but malnutrition results from nutrient malabsorption, impaired nutrient use, increased nutrient loss, or increased nutrient needs such as pregnancy, neonatal growth, disease states, or cold weather). Inadequate diets can involve imbalances between dietary nutrients

## Pathologic Basis of Veterinary Disease, 4th Edition

---

(e.g., copper deficiency and molybdenum excess, and vitamin E deficiency and excess dietary fatty acids). Diets inadequate in one nutrient may be inadequate in multiple nutrients, or there may be a greater deficiency in one nutrient relative to the others (e.g., starvation, the diet may be inadequate in protein, fats, and carbohydrates, and vitamins and minerals, or there may be a greater deficiency in protein relative to other nutrients). A variety of nutritional deficiencies result in similar cutaneous lesions. The lesions heal when the animal is fed a balanced diet. Deficiencies affecting the skin include protein-energy malnutrition (starvation), fatty acid deficiency, vitamin deficiencies (A, C, E), and deficiencies of riboflavin, pantothenic acid, biotin, niacin, iodine, cobalt, copper, and zinc. A few selected deficiency conditions are described.

17.2.6.2

### PROTEIN-CALORIE MALNUTRITION

Protein-calorie malnutrition results in a range of clinical syndromes from inadequate dietary intake of protein and calories to meet the needs of the body. Often diets are deficient in multiple components including protein, carbohydrates, and fats, which together are responsible for the total caloric intake. Deficiency of calories per se results in weight loss (adults) or retarded growth (young growing animals) and reduced subcutaneous fat and muscle, producing a thin, emaciated appearance. Increased energy demands such as pregnancy or cold weather can worsen the severity of the malnutrition, leading to ketosis in pregnant sheep, birth of weak neonates or dead fetuses, lack of estrus cycles, and death. A greater deficiency of protein relative to calories also results in malnutrition, referred to herein as “protein deficiency.” In early stages, protein deficiency malnutrition resembles that from deficiency of calories, and results in weight loss and reduced production (e.g., milk) in adults and reduced growth in young animals. In addition, prolonged protein deficiency also results in edema caused by the reduction in the concentration of the serum protein, albumin. Because of the requirement of protein for the production of hair coat, the hair coat of malnourished animals (protein-calorie malnutrition and protein deficiency) is thin and dull, with failure to shed or to complete the normal hair cycle. The epidermis, dermis, and adnexa are atrophic with reduced subcutaneous fat and muscle, and surface scales (hyperkeratosis) can be present. In long-standing severe protein deficiency, dermal and subcutaneous edema is present.

1226

1227

17.2.6.3

### ZINC DEFICIENCY

Zinc deficiency occurs chiefly in pigs and dogs and is of less importance in ruminants. It results from diets containing high concentration of phytic acid (binds zinc), low concentration of zinc, or high concentration of calcium (reduces absorption of zinc), or from inherited defective absorption or metabolism.

17.2.6.3.1

#### Zinc Deficiency in Pigs

Zinc deficiency, although once common in pigs, occurs infrequently today because of dietary supplementation. Gross lesions are generally symmetrical, circumscribed, reddened macules that develop first on the ventral abdomen and medial thighs, and spread to the lower limbs especially over joints, periocular areas, pinnae, snout, scrotum, and tail. The macular lesions progress to papules and plaques that become covered with scales and crust. The crusts thicken, and develop fissures filled with debris including soil and bacteria. The fissures provide a route of entrance for bacteria that can cause infection including the development of subcutaneous abscesses. Microscopically, the lesions are parakeratosis, hypergranulosis, acanthosis, and pseudoepitheliomatous hyperplasia. Secondary bacterial invasion results in epidermal pustular dermatitis and folliculitis. The fissures filled with debris can become infected by mixed populations of bacteria and lead to the development of subcutaneous abscesses.

### Canine Zinc Responsive Dermatitis

This dermatosis occurs in two forms. One form occurs principally in Siberian huskies and Alaskan malamutes, but other large-breed dogs can be affected. Alaskan malamutes have an inherited reduced ability to absorb zinc from the intestine. Scaling and crusting develop in the skin around the mouth, chin, eyes ([Fig. 17-72](#)), external ears, pressure points, and footpads. The second form of zinc deficiency occurs in rapidly growing pups of large-breed dogs fed diets low in zinc or high in calcium or phytates, which can interfere with zinc absorption. Clinically dogs with this form have scaly plaques located on those areas of the skin subjected to repeated trauma (e.g., elbows and hocks), the footpads, and planum nasale. Microscopically, there is marked diffuse parakeratosis ([Fig. 17-72, B](#)) that extends into the hair follicles, and an accompanying superficial perivascular lymphocytic and sometimes eosinophilic dermatitis. Another disorder, generic dog food dermatosis, a largely historic disease that occurred in the 1980s in dogs fed generic dog foods, has clinical and histologic lesions similar to those of canine zinc responsive dermatosis. However, dogs with generic dog food dermatosis had a more rapid onset of lesions, and also had systemic signs such as fever, depression, lymphadenopathy, and pitting edema of the dependent areas. The acute onset and systemic signs suggested that more than zinc deficiency played a role in generic dog food dermatosis.

Fig. 17-72 **Zinc responsive dermatosis, skin, dog. A**, Siberian husky. Periocular skin is thickened, alopecic, pigmented, and covered by tightly adherent scale. In Siberian huskies and Alaskan malamutes in particular, scaling and crusting develop in the skin around the mouth, chin, eyes, external ears, pressure points, and footpads. **B**, Note the papillary epidermal hyperplasia with marked parakeratosis. The parakeratotic hyperkeratosis and acanthosis form the thickened adherent scale. Although epidermal hyperplasia and parakeratosis are features of zinc-responsive dermatosis, they also occur in other conditions (such as superficial necrolytic dermatitis, chronic surface trauma, and nasal parakeratosis). Therefore breed, lesion distribution, and other features in the clinical history or clinical chemistry analysis are important in differential diagnosis. H&E stain. (**A and B**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.6.3.3 Lethal Acrodermatitis of Bull Terriers

Lethal acrodermatitis is an autosomal recessive inherited disease of defective zinc metabolism in white bull terriers. The exact cause or pathogenesis of the disorder is not known. Although defective zinc metabolism and/or absorption are thought to play a role, affected dogs do not respond to oral or parenteral zinc supplementation. The concentrations of serum zinc and copper are low in affected bull terriers compared with those of control dogs, suggesting that copper deficiency might contribute. Lesions generally begin between 6 and 10 weeks of age. Most affected dogs are dead by 15 months of age, usually because of bronchopneumonia. The thymus is small or absent, and T lymphocytes are deficient in lymphoid tissues, likely contributing to immunodeficiency and increasing the potential of infection. Cutaneous lesions begin between the digits and on footpads and progress to involve mucocutaneous areas, especially of the face. Severe interdigital pyoderma, paronychia (inflammation of the skin around the claws), and villous thickening and fissuring of footpad keratin ensue. Exfoliative dermatitis can also develop on pinnae, external nose, elbows, hocks, and, in some dogs, can become more generalized, with crusting, ulceration, and secondary pyoderma. Microscopically, the principal lesions are extensive diffuse parakeratotic hyperkeratosis, responsible for the exfoliative dermatitis, and accompanying acanthosis. Lesions of secondary infection consist of epidermal pustular dermatitis and folliculitis.

### 17.2.6.3.4 Dietary Zinc Deficiency in Ruminants

Dietary zinc deficiency has been reported in cattle, sheep, and goats. Cutaneous lesions include alopecia, scaling, and crusting of the skin of the face, neck, distal extremities, and mucocutaneous junctions. In uncomplicated cases, microscopic lesions consist of parakeratosis and sometimes hyperkeratosis.

### 17.2.6.3.5 Hereditary Zinc Deficiency

Hereditary zinc deficiency (lethal trait A-46, hereditary parakeratosis, hereditary thymic aplasia) is an autosomal recessive inherited form of zinc deficiency that has been reported in young calves (Friesian and Black Pied Danish cattle of Friesian descent in Europe, and shorthorn cattle in the United States). The disease is due to intestinal malabsorption of zinc, and lesions resolve with zinc supplementation. The disease is multisystemic. Skin lesions usually begin at 1 to 2 months of age, and without zinc supplementation, calves usually die within a few months from secondary infections associated with immune dysfunction. Skin lesions begin on the nose and spread to periocular areas, pinnae, intermandibular space, and distal extremities including coronary bands. Ventral abdominal, flank, and perineal skin can also be affected. Lesions consist of erythema, exudation, crusting, scaling, and a rough hair coat that fades to lighter color. The calves have thymic hypoplasia, reduced humoral and cell-mediated immunity, and secondary infections. The major histologic lesion is marked diffuse parakeratotic hyperkeratosis (parakeratosis). There also can be perivascular edema and dermatitis with neutrophilic exocytosis forming crusts colonized by cocci.

### 17.2.6.4 COPPER DEFICIENCY

Copper is an essential component of tyrosinase, an enzyme critical in melanogenesis. Animals with copper deficiency or depressed tyrosinase activity have depigmented hair or wool. Copper deficiency can be due to simple deficiency or secondary to excessive dietary sulfate and molybdenum, which interfere with absorption. This pigmentary disorder is seen primarily in cattle and sheep. Affected cattle with normally

## Pathologic Basis of Veterinary Disease, 4th Edition

---

black coats become rusty-brown and develop “spectacle” lesions of depigmented hair around the eyes. Black sheep develop intermittent bands of light-colored wool corresponding to periods of restricted availability of copper. The deficiency of copper also affects the physical nature of the wool or hair. In sheep, the wool has less crimp, prompting the colloquial name of “string” or “steely” wool. The straightness of the wool is due to inadequate keratinization, probably caused by imperfect oxidation of sulfhydryl groups in prekeratin, a process that involves copper.

### 17.2.6.5 VITAMIN E DEFICIENCY

Cats fed diets containing an excess of dietary fatty acids such as canned red tuna can develop inflammation of the subcutaneous and abdominal fat (steatitis). This condition develops when the diet is high in fat and when food processing or oxidation inactivate vitamin E. Vitamin E has a number of functions that contribute to its role as an antioxidant that stabilizes lysosomes. Grossly, the subcutaneous fat contains firm, nodular, yellow to orange masses. Microscopic lesions consist of fat necrosis that stimulates a lobular to diffuse neutrophilia followed by granulomatous inflammatory response. Macrophages and multinucleated giant cells contain ceroid pigment, which is responsible for the yellow to orange color of the affected fat.

1228

1229

### 17.2.6.6 VITAMIN A RESPONSIVE DERMATOSIS

Vitamin A responsive dermatosis is a rare disorder primarily occurring in cocker spaniels, although a few other breeds of dogs have been affected. Because lesions respond to vitamin A therapy and relapse when treatment is withdrawn, vitamin A plays a role in the pathogenesis. However, vitamin A deficiency is not the cause of the lesions, as plasma concentrations of vitamin A are within the normal range. Vitamin A might contribute to lesion resolution by influencing epithelial differentiation. Gross lesions consist of generalized scaling, dry hair coat, and hyperkeratotic plaques with large “fronds” of stratum corneum extending from distended follicular openings (large open comedones). The plaques are most prominent in the ventral and lateral thorax and abdominal skin, but can also occur on the face and neck. Microscopic lesions consist of mild orthokeratotic hyperkeratosis, mild irregular epidermal hyperplasia, and follicles markedly distended by hyperkeratosis.

### 17.2.7 DISORDERS OF EPIDERMAL GROWTH OR DIFFERENTIATION

#### 17.2.7.1 PREDOMINANT EPIDERMAL HYPERKERATOSIS (SCALE)

##### 17.2.7.1.1 Primary Idiopathic Seborrhea

Primary idiopathic seborrhea is a disorder of epidermal hyperproliferation that results in increased production of corneocytes and visible scale. It occurs most commonly in dogs and less commonly in horses and cats. Most experimental work has been performed in cocker spaniels. The pathogenesis of the disease involves hyperproliferation of the epidermis, hair follicle infundibulum, and sebaceous glands. The basal cell labeling indices are 3 or 4 times higher in cocker spaniels with seborrhea than in normal dogs. The hyperproliferation results in reduction in the epidermal turnover time to about one third (e.g., from 22 days to 8 days in the cocker spaniel). In the cocker spaniel the disorder appears to be the result of a primary cellular defect in the keratinocyte, as the epidermal cells remain hyperproliferative when grown in culture and after being grafted onto the dermis of normal dogs. In seborrhea, quantitative studies on sebum production have not been performed, but it is known that there is a relative increase in

## Pathologic Basis of Veterinary Disease, 4th Edition

free fatty acids and a relative decrease in diester waxes on the surface of the seborrheic skin of various breeds. In addition, there is a change from nonpathogenic resident bacteria to pathogenic, coagulase-positive staphylococci. Clinically, two forms of seborrhea have been described, a dry form (seborrhea sicca) with dry skin and white to gray scales that exfoliate (Fig. 17-10), and a greasy form (seborrhea oleosa) with scaling and excessive brown to yellow lipids that adhere to the surface of the skin and hair. An animal can have seborrhea sicca in some areas of the body and seborrhea oleosa in others. Microscopic lesions include marked hyperkeratosis of the epidermis and follicular epithelium. The epidermis has a papillary appearance due to widening of follicular ostia by the follicular hyperkeratosis (Fig. 17-10). Comedones (follicles dilated with a plug of follicular stratum corneum and sebum) are present in some animals. At the edges of follicular ostia, foci of parakeratosis form over a spongiotic epidermis containing a few scattered leukocytes. The superficial dermis is congested and edematous.

17.2.7.1.2

### Ichthyosis

Ichthyosis is an inherited cutaneous disease seen principally in dogs and cattle. It has also been reported in llamas and pigs. The skin is thickened by marked hyperkeratosis and can crack into plates resembling fish scales, thus the origin of the name. The basic defect is increased adherence of keratinocytes, which prevents normal desquamation. In cattle, two forms of the disease have been described. One (ichthyosis fetalis) is lethal, and most calves are stillborn or die within days of birth. Grossly and microscopically the skin is alopecic and covered by thick cornified plaques separated by fissures. Fissuring of the skin leads to exudation of protein, and secondary bacterial and fungal infections that often lead to death or euthanasia. In the second and less severe form (ichthyosis congenita), lesions in some calves are mild at birth and progress with age. The skin becomes thickened, folded, and covered by scale, and partial alopecia develops. More severe lesions are seen where hair is shorter, particularly on the limbs, abdomen, and nose. In dogs, ichthyosis is rare and usually present at birth. Grossly, there are scales adherent to the epidermis, which shed in sheets attached to hair shafts (Fig. 17-73). There can be marked thickening of nasal planum and digital pads by accumulated stratum corneum forming fronds. Alopecia is sometimes present. In addition to marked epidermal and follicular hyperkeratosis, hypergranulosis, keratinocyte vacuolation, and reticular degeneration are seen in the skin of some affected animals.

## Pathologic Basis of Veterinary Disease, 4th Edition

17.2.7.1.3

### Sebacaceous Adenitis

Sebacaceous adenitis, inflammation of sebaceous glands, is probably immune-mediated. Sebaceous adenitis occurs most commonly in dogs. Lesions are diffuse in the longer-haired breeds and multifocal, annular, and serpiginous in shorter-haired breeds. Microscopic lesions include inflammation of the sebaceous glands (Fig. 17-31), and in some dogs, extensive orthokeratotic hyperkeratosis. Chronically affected dogs have no remaining sebaceous glands, but mild residual inflammation and fibrosis are present in the perifollicular dermis near the isthmus (site normally occupied by sebaceous glands).

17.2.7.1.4

### Hyperkeratosis of Nasal Planum or Footpads in Dogs

Nasal and/or digital hyperkeratoses have a variety of underlying causes, including infectious disease (e.g., canine distemper [see Chapter 14], leishmaniasis, putative papillomavirus infection), immune-mediated disorders (e.g., pemphigus foliaceus and lupus erythematosus), familial or inherited disorders (e.g., idiopathic seborrhea, familial footpad hyperkeratosis of Irish terriers and Dogue de Bordeaux, ichthyosis, familial nasal hyperkeratosis, nasal parakeratosis of the Labrador retriever), metabolic or nutritional disease (e.g., superficial necrolytic dermatitis, zinc-responsive dermatosis), adverse reaction to drug therapy, and neoplasia (e.g., cutaneous lymphoma) (Box 17-12). In some cases, an underlying cause is not determined, thus the condition is considered to be idiopathic (occurs most commonly in old dogs). Some of the disorders in which nasal or digital hyperkeratosis is a feature also have skin lesions in other sites, and systemic disease can be present. Gross lesions on the footpads or nasal planum include a dry, thick, irregular and rough surface in which crusts, fissures or erosions can develop (Figs. 17-11 and 17-16). The edges of the footpads and non-weight-bearing pads are more severely affected because friction on weight-bearing surfaces wears through some of the excessively thick stratum corneum. Histologic lesions reflect the underlying cause. In the idiopathic nasodigital hyperkeratosis of old dogs, irregular epidermal hyperplasia with marked orthokeratotic to parakeratotic hyperkeratosis is present. In familial nasal parakeratosis, there is variable parakeratotic hyperkeratosis with intraepidermal serum and leukocytic exocytosis. The dermis has perivascular to interface or interstitial mixed inflammation. In familial footpad hyperkeratosis, there is moderate to extensive epidermal acanthosis and marked diffuse orthokeratotic hyperkeratosis in which the surface stratum corneum forms many papillary projections.

### 17.2.7.2 **PREDOMINANT FOLLICULAR HYPERKERATOSIS (COMEDONES)**

Comedones ([Table 17-5](#)) occur in numerous skin disorders, including those associated with surface trauma (callus, actinic dermatosis), endocrine dermatosis (especially hyperadrenocorticism), nutritional or inherited disorders of cornification (primary seborrhea, vitamin A responsive dermatosis), and in some disorders associated with follicular infection (especially demodicosis). In addition, comedones are prominent in two conditions wherein the comedones are considered a major feature of the disease.

#### 17.2.7.2.1 **Schnauzer Comedo Syndrome**

Schnauzer comedo syndrome affects some miniature schnauzers and probably has an inherited basis. Gross lesions develop on the dorsum of the back and consist of comedones, papules and crusts. Histologic lesions consist of follicles distended with a plug of follicular stratum corneum and sebum (comedones). Because the follicular opening is connected to the epidermis, the dilated follicles can contain coccoid bacteria. The dilated follicles can rupture (furunculosis) and release contents into the dermis resulting in a foreign body and bacterial infection.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.7.2.2 Acne

Feline acne is a disorder of follicular cornification in the skin of the chin, lower lip, and less commonly upper lip. Cats of a variety of ages, sexes, and coat lengths are affected. Gross lesions consist of comedones that can progress to papules, crusts, nodules, and diffuse swelling. Histologic lesions begin as mild follicular hyperkeratosis and progress to comedones, which can become secondarily infected by bacteria, rupture (furunculosis), and cause panniculitis and cellulitis.

Canine acne is a chronic disorder that develops in the skin of the chin and lips of young dogs, usually with short hair coats. The cause of the disorder is not known, but a follicular cornification disorder has not been definitively documented. Early lesions consist of follicular papules and comedones that with time enlarge to nodules that can ulcerate and drain. Histologically early lesions consist of moderate to marked follicular hyperkeratosis (the papules and comedones), and later of folliculitis, furunculosis, and draining sinuses (the nodular, ulcerated, and draining lesions).

### 17.2.7.3 PREDOMINANT EPIDERMAL HYPERPLASIA (LICHENIFICATION OR CRUSTS)

#### 17.2.7.3.1 Secondary Seborrhea

Secondary seborrhea is not a primary disorder of cornification; however, it clinically resembles the primary cornification disorders (dry exfoliative or greasy adherent scales) and thus needs to be differentiated from them. Secondary seborrhea is common, and is caused by a variety of unrelated cutaneous disorders such as allergy, ectoparasitism, fungal infection, dietary deficiency, endocrine disease, and internal diseases. The lesions of secondary seborrhea resolve completely if the underlying disease is eliminated. Microscopic changes include epidermal and follicular hyperkeratosis with or without parakeratosis plus the lesions associated with the underlying disease.

#### 17.2.7.3.2 Porcine Juvenile Pustular Psoriasiform Dermatitis (Pityriasis Rosea)

This disorder develops in suckling and young pigs (3 to 14 weeks of age), usually resolves spontaneously by 4 weeks of onset, and is thought to be inherited. A few piglets in the litter or entire litters can be affected. Lesions are symmetric and develop on the abdomen, groin, and medial thigh and begin as small papules covered by brown crusts. The lesions coalesce and spread, and develop into umbilicated plaques with white centers and erythematous, scaly borders that can progress into mosaic patterns (Fig. 17-74). These clinical lesions resemble those of dermatophytosis, swinepox, and dermatosis vegetans, from which they need to be differentiated, but otherwise the clinical lesions are of no significance. Microscopically, the early histologic lesions are superficial and deep perivascular neutrophilic, eosinophilic, and mixed mononuclear dermatitis. Epidermal spongiosis and leukocytic exocytosis result in spongiform pustules. Later lesions consist of marked psoriasiform epidermal hyperplasia (regular epidermal hyperplasia with epidermal ridges of uniform length and width) and parakeratotic cellular crust.

1231

1232

Fig. 17-74 **Porcine juvenile pustular psoriasiform dermatitis (pityriasis rosea), skin, pig. A**, Abdomen. Note the circular to serpiginous (wavy) lesions with distinct raised and reddened border and the adjacent scale. These lesions need to be differentiated from those of edematophytosis, swinepox, and dermatosis vegetans. **B**, Note the epidermal hyperplasia (acanthosis with elongated rete ridges) and intraepidermal pustules. The dermis contains diffuse accumulations of neutrophils and mixed mononuclear inflammatory cells. The disease receives its name from the juvenile age of onset, the formation of epidermal pustules, and the exaggerated regular epidermal hyperplasia (psoriasiform hyperplasia). H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.7.3.3 Equine Coronary Band Dystrophy

Equine coronary band dystrophy is a condition of unknown etiology and pathogenesis. Clinically, the coronary band (coronary border of hoof) is thickened, crusty, and scaly. Cracks and fissures can lead to lameness. The chestnuts and ergots (cornified protuberances considered to be vestiges of the first, second, and fourth digits) are similarly affected and can be ulcerated. Usually all four limbs are affected; however, the lesion may not involve the entire coronary band. Histologically, the epidermis of affected areas has marked papillary epidermal hyperplasia (Fig. 17-12) and marked orthohyperkeratosis to parakeratotic hyperkeratosis. In some areas, there is ballooning degeneration of keratinocytes. Dermal inflammation is minimal unless secondary infection is present. The diagnosis is made by ruling out the various differential diagnoses, including pemphigus foliaceus, hepatocutaneous syndrome, bacterial or fungal infection, selenium toxicosis, mite infestation, and eosinophilic exfoliative dermatitis. The condition is chronic and treatment palliative. Although the condition affects adult horses of any breed, draft breeds are considered predisposed.

### 17.2.8 DISORDERS OF PIGMENTATION

Melanin pigments are responsible for the coloration of the hair, skin and eyes, and also play an important role in photoprotection. Melanin is synthesized by melanocytes, which are dendritic cells originating as melanoblasts in the neural crest. Melanoblasts develop in the neural crest and migrate to peripheral sites including the basal and lower spinous layers of the epidermis, hair follicles, and dermis. Melanoblasts differentiate into melanocytes, and synthesize melanosomes and melanin. Tyrosinase, a copper-containing enzyme, plays a critical role in the synthesis of melanin. Genetic mutations affecting any of the steps in the formation of melanin can lead to hereditary hypopigmentation. Many types of exogenous influences, such as inflammation, UV radiation, endocrinopathies, autoimmune diseases, and nutritional status, can affect melanocytes in the skin, resulting in acquired hypopigmentation or hyperpigmentation. Examples of some of the disorders include Chédiak-Higashi syndrome, color mutant (dilution) alopecia, the Maltese dilution of cats, leukoderma and/or leukotrichia of Doberman pinschers and rottweilers, periocular leukotrichia in Siamese cats, and Arabian fading syndrome. Immune-mediated disorders associated with depigmentation include discoid lupus erythematosus and uveodermatologic syndrome (VKH-like disease).

#### 17.2.8.1 HYPOPIGMENTATION

Disorders associated with reduced pigment can (1) be inherited or acquired, (2) involve skin or hair, (3) be generalized or localized, or (4) be idiopathic or linked with other diseases. Reduction in pigmentation of the skin is leukoderma, and of the hair is leukotrichia. Leukoderma and leukotrichia can occur independently. They can result from a decrease in melanin (hypomelanosis), a complete absence of melanin (amelanosis), or from a loss of existing melanin (depigmentation). These events result from either an absence of the pigment-synthesizing melanocytes or from a failure of melanocytes to produce normal amounts of melanin or to transfer it to adjacent keratinocytes. Because copper is a component of tyrosinase, production of melanin pigment is dependent on copper, thus copper deficiency can result in reduced pigmentation.

1232

1233

### Inherited Hypopigmentation

Hereditary hypopigmentation can be divided into melanocytopenic hypomelanosis, characterized by the absence of melanocytes in affected areas, and melanopenic hypomelanosis, in which melanocytes are present but defective. Hypopigmentation can be localized, focally extensive, or generalized.

Syndromes analogous to the human Waardenburg's syndrome have been reported in cats, dogs, and horses. In this melanocytopenic hypomelanosis, there is failure of melanoblasts to migrate from the neural crest into the skin, or failure to survive in the skin. Affected animals typically have white coats and blue or heterochromatic irides, and are deaf. In cats, this has been shown to be a result of an autosomal dominant mutation with complete penetrance for loss of pigmentation and incomplete penetrance for deafness. In dogs, this syndrome has been described in breeds such as the Dalmatian, bull terrier, Sealyham terrier, collie, and Great Dane. A syndrome analogous to human Waardenburg type-4 (Hirschsprung's disease) has been reported in American Paint horses in which white foals from overo mares are born with aganglionic colons. These foals develop colic from greatly distended colons, and die shortly after birth.

Piebaldism is also a form of genetic melanocytopenic hypomelanosis resulting in multifocal white patches in which there is an absence of melanocytes because of either a congenital failure of melanoblasts to migrate from the neural crest to the skin, or by their inability to survive and proliferate in the skin. Piebaldism has been seen in many species including horses, dogs such as the Dalmatian, cats, and cattle.

Vitiligo is a melanocytopenic hypomelanosis of human beings and animals, which is characterized by gradually expanding pale macules that are often symmetrical or segmental in distribution. The immediate cause of vitiligo is the destruction of melanocytes. It is considered to be a genetic amelanosis inherited as an autosomal recessive trait in animals. Theories regarding the pathogenesis of this disease include autoimmune destruction of melanocytes, a neurogenic theory involving release of a neurochemical from peripheral nerves that inhibits melanogenesis, a self-destruction theory that involves failure of protection of melanocytes against the toxic effects of melanin precursors, or a combination of factors. Vitiligo has been described in the dog, cat, horse, and cattle. The condition is best characterized in Belgian tervurens. The depigmentation in this breed occurs chiefly on the pigmented skin and mucous membranes of the face and mouth in young adult dogs. Histologic examination of affected skin shows an epithelium devoid of both pigment granules and DOPA-positive cells. Electron microscopy confirms the lack of melanocytes in the lesions, their place being taken by Langerhans' or indeterminate dendritic cells.

The various forms of albinism are examples of melanopenic hypomelanosis. In albino animals and human beings, melanocytes are present and normally distributed but are defective in function and fail to synthesize melanin. The extent of the biochemical defect varies, so that albinism covers a spectrum from amelanosis, oculocutaneous albinism, through graded pigmentary dilution. Oculocutaneous albinisms and pigment dilutions are inherited as autosomal recessive traits. In albino animals with white hair and skin, and translucent irides, there is a mutation in the tyrosinase gene resulting in no residual enzyme activity.

CH&Eacute;diak-Higashi syndrome in human beings, Hereford, Brangus, and Japanese Black cattle; Persian cats; and various other animal species is an example of partial albinism and is inherited as an autosomal recessive trait. While melanin is produced, there is a mutation of the beige gene, which plays a major role in generating cellular organelles. This results in a membrane defect leading to the formation

## Pathologic Basis of Veterinary Disease, 4th Edition

of giant melanosomes that are transferred with difficulty to the keratinocytes. The clumping of these giant melanosomes produces the color dilution effect. CH&Eacute;diak-Higashi syndrome is discussed with the hematopoietic system (see [Chapter 13](#)).

Cyclic hematopoiesis (cyclic neutropenia), a lethal hereditary disease of collie dogs, is caused by an autosomal recessive gene with a pleiotropic effect on coat color dilution. Affected dogs are silver-gray. The abnormal hair pigmentation results from the diminished formation of melanin from its precursor tyrosine rather than from pigment clumping. The normal collie coat color is restored in animals receiving bone marrow transplants to correct cyclic hematopoiesis. The hematological aspects of this disease are considered with the hematopoietic system (see [Chapter 13](#)).

Coat color dilution has been reported in many species. It occurs in many breeds of dogs, cats, horses, and cattle, but is particularly common in Siamese cats. The pale coat coloration is due to clumping of large melanin granules in hair shafts, hair matrix cells, and sometimes in the epidermis. In cats, dilute coat color is thought to be a result of an autosomal recessive trait (Maltese dilution).

1233

17.2.8.1.2

### Acquired Hypopigmentation

1234

Acquired hypopigmentation follows damage to the epidermal melanin unit by various insults, including trauma, inflammation, radiation, contactants, endocrinopathies, infections and nutritional deficiencies. In general, the severity of the injury determines whether an insult will result in hypopigmentation or hyperpigmentation. Mild injury results in pigmentary incontinence and epidermal hypopigmentation from death of melanin containing keratinocytes. However, hyperpigmentation can occur, possibly from release of melanocyte-stimulating factors from surviving keratinocytes and subsequent increase in production of melanosomes. It is thought that these factors are preset in normal epidermis, but their level or activity is increased in response to stimulation or keratinocyte stress. In contrast, severe injury results in the death of melanocytes, which do not regenerate, and thus there is no repigmentation.

Cutaneous depigmentation in dogs and horses can result from contact with rubber. The monobenzene ether of hydroquinone, a common ingredient in rubber, inhibits melanogenesis. In horses lesions result from contact with equipment such as rubber bit guards, crupper straps, or with feed buckets (lips, buttocks, face). In dogs lesions result from contact with rubber dishes or toys (lips or nose).

In dogs, hypopigmentation can occur in immune-mediated diseases such as lupus erythematosus, dermatomyositis, and uveodermatologic syndrome (see Selected Autoimmune Reactions). The hypopigmentation develops from injury and subsequent loss of the melanin-containing keratinocytes or melanocytes. Leukotrichia (depigmentation of hair) can be seen in the healing stage of alopecia areata, an immune-mediated condition characterized clinically by alopecia, and microscopically by lymphocytic inflammation of the hair bulb.

17.2.8.2

### HYPERPIGMENTATION

17.2.8.2.1

#### Secondary Hyperpigmentation

Hyperpigmentation can result from inflammation, irritation, and metabolic disorders. Consequently hyperpigmentation is seen in all species with epidermal melanin pigment. Hypermelanosis results from an increased rate of melanosome production, an increase in melanosome size, or an increase in the degree of melanization of the melanosome. It is usually associated with an accelerated melanocyte

## Pathologic Basis of Veterinary Disease, 4th Edition

---

turnover with an increased number of melanosomes, as occurs following trauma and ultraviolet light exposure.

### 17.2.8.2.2 Acanthosis Nigricans

Primary idiopathic acanthosis nigricans is considered a genodermatosis (genetically determined skin disorder) of young dachshunds. The disease is manifested by bilateral axillary hyperpigmentation, lichenification, and alopecia, which can involve large areas and include secondary seborrhea and pyoderma. Histological examination reveals hyperplastic dermatitis with orthokeratotic and parakeratotic hyperkeratosis, acanthosis and rete ridge formation. All layers of the epidermis are heavily melanized. Spongiosis, neutrophilic exocytosis and serous crusts can also be present. The dermal inflammatory reaction is mild, pleomorphic in cell type, and superficial perivascular in location. The term “acanthosis nigricans” has also been used to encompass a variety of chronic inflammatory and pruritic disorders that in their chronic form are manifested by axillary or more diffuse lichenification, alopecia, and hyperpigmentation. Consequently, the diagnosis of primary acanthosis nigricans requires clinical correlation together with the histologic findings to support the diagnosis in a young dachshund with compatible lesion distribution.

### 17.2.8.2.3 Nonneoplastic Pigmented Macules or Plaques

#### 17.2.8.2.3.1 Lentigines (focal macular plaques)

Lentigines are rare, nonneoplastic, well circumscribed, macular to slightly raised plaques found most often on the mucocutaneous junctions of the mouth, eye, nose, and footpads. Histologically, lentigenes are characterized by irregular epidermal hyperplasia, hyperpigmentation, and increased numbers of pigmented melanocytes. Lentigines are often multifocal and have been described in dogs and cats. The lesions are of no significance except that they can be confused clinically with melanoma or epidermal pigmented plaques.

#### 17.2.8.2.3.2 Pigmented epidermal plaques

See Viral Infections, Papillomaviruses.

### 17.2.9 MISCELLANEOUS SKIN DISORDERS

#### 17.2.9.1 DISORDERS CHARACTERIZED BY INFILTRATES OF EOSINOPHILS OR PLASMA CELLS

These diseases are listed in [Box 17-13](#). In addition to the syndromes discussed herein, eosinophils are often a prominent feature of hypersensitivity or parasitic dermatoses, especially in cats and horses, and are also often a feature in feline herpesvirus facial dermatitis.

#### 17.2.9.1.1 Eosinophilic Plaques

These common lesions of the skin of cats occur on the abdomen and medial thigh and are thought to be associated with hypersensitivity reactions. Lesions consist of raised, variably sized erythematous,

1234

pruritic, and eroded to ulcerated plaques. Microscopically, epidermal lesions include acanthosis, variable spongiosis, erosion, and ulceration, accompanied by superficial and deep, perivascular to diffuse, predominantly eosinophilic dermatitis.

### 17.2.9.1.1.1

#### Box 17-13 Disorders Characterized by Infiltrates of Eosinophils or Plasma Cells

Eosinophilic plaques

Eosinophilic granulomas

Nasal eosinophilic folliculitis and furunculosis in dogs

Hypereosinophil syndromes with systemic signs or lesions

Multisystemic eosinophilic epitheliotropic disease in the horse

Feline hypereosinophilic syndrome

Eosinophilic dermatitis with edema in the dog

Feline plasma cell pododermatitis

Hypersensitivity and parasitic dermatitis (see Mechanisms of Tissue Damage in Hypersensitivity Reactions)

Feline herpesvirus facial dermatitis (see herpesvirus section)

### 17.2.9.1.2

#### Eosinophilic Granulomas (Collagenolytic Granulomas)

Eosinophilic and granulomatous lesions with brightly eosinophilic, granular to amorphous material bordering collagen fibers and somewhat obscuring the fiber detail (flame figures) occur in cats, dogs, and horses. The causes of these syndromes are poorly understood. The tinctorial change can develop in any lesion with large numbers of eosinophils such as reactions to parasites, foreign bodies (including hair), or in mast cell tumors. Eosinophils congregate and degranulate near collagen bundles causing the tinctorial change. Eosinophil degranulation results in release of a wide range of toxic granule proteins (e.g., major basic protein), enzymes (peroxidase, collagenase), cytokines (IL-3, IL-5, GM-CSF), chemokines (IL-8), and lipid mediators (leukotrienes and platelet-activating factor) augmenting an inflammatory response. Gross lesions include papules, nodules, plaques (sometimes linear), and ulcers in the skin (Fig. 17-23). Nodular or ulcerated lesions can also develop in the oral mucosa of dogs and cats, and footpads of cats. Microscopically, nodular dermatitis (or stomatitis) consists of an inflammatory response with a prominence of eosinophils, flame figures, and macrophages, some of which are multinucleated (Fig. 17-23). Collagen lysis develops in some lesions, likely a secondary event caused by the proteolytic enzymes (e.g., collagenase). Some indolent ulcers on the upper lip of cats have areas of flame figures and granulomatous inflammation and are considered to be eosinophilic granulomas.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 17.2.9.1.3 Nasal Eosinophilic Folliculitis and Furunculosis in Dogs

Nasal eosinophilic folliculitis and furunculosis develops primarily on the dorsal and lateral surfaces of the nose of young dogs, and is thought to be a result of arthropod bites (bees, wasps, spiders). Lesions develop acutely, and are often painful swollen areas that rapidly ulcerate and can drain bloody fluid. Lesions can progress to involve the periocular, pinna, and sometimes the glabrous ventral abdominal skin. Because lesions develop rapidly and appear clinically severe, biopsy samples are typically collected early in the course of the disease. At this time, microscopic lesions consist of ulceration, superficial and deep interstitial eosinophilic to mixed inflammation with eosinophilic folliculitis and furunculosis.

### 17.2.9.1.4 Hypereosinophilic Syndromes with Systemic Signs or Lesions

#### 17.2.9.1.4.1 Multisystemic eosinophilic epitheliotropic disease in the horse

This generalized, exfoliative dermatitis of horses is of unknown etiology; however, one case report documents the coexistence of an intestinal T-lymphocyte lymphoma and postulates a role for tumor cell overproduction of IL-5, a powerful eosinophilopoietin. Initial cutaneous lesions include dry scales and serous exudates of the epithelium of the skin of the head, coronary bands, and oral mucosa. The lesions progress to generalized excoriations with ulceration and alopecia. Secondary infections are common. Histologically there is superficial and deep, perivascular to interstitial, eosinophilic lymphoplasmacytic, and sometimes granulomatous dermatitis with irregular epidermal hyperplasia and orthokeratotic and parakeratotic hyperkeratosis. Eosinophils, lymphocytes, and apoptotic keratinocytes can be prominent in the epidermis, and eosinophilic folliculitis, furunculosis, and flame figures are occasionally seen. The dermatitis is accompanied by a similar inflammatory response with fibrosis in other organs including the alimentary tract, pancreas, liver, uterus, and bronchial epithelium. Clinically, the horses lose weight and become progressively debilitated.

#### 17.2.9.1.4.2 Feline hypereosinophilic syndrome

Feline hypereosinophilic syndrome is a rare multisystemic disorder of unknown cause that is associated with moderate to marked peripheral eosinophilia and infiltrates of mature eosinophils in multiple organ systems, sometimes including the skin. Middle-aged female cats are more often affected. Gross lesions of the skin include erythema and excoriations associated with severe pruritus.

1235

1236

Histologically, there is superficial and deep, perivascular dermatitis with prominent eosinophils. Clinical signs include anorexia, diarrhea, weight loss, and vomiting.

#### 17.2.9.1.4.3 Eosinophilic dermatitis with edema in the dog

Eosinophilic dermatitis with edema is a newly described condition affecting adult dogs of a variety of breeds, although Labrador retrievers may be overrepresented. The cause is not known, but a hypersensitivity reaction to medications, arthropod bites, or other antigens is suspected. Gross lesions consist of extremely erythematous macules that progress and coalesce into arciform and serpiginous plaques. Facial or generalized pitting edema is often seen. Lesions involve the pinnae, ventral abdomen and thorax, and less often the extremities. Histological lesions consist of diffuse, predominantly eosinophilic dermatitis, vascular dilation, and edema. Eosinophil aggregation and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

degranulation are seen in some lesions. Depression, hypoproteinemia, and pyrexia are present in some dogs.

17.2.9.1.5

### Plasma Cell Pododermatitis

Feline plasma cell pododermatitis is an uncommon condition of undetermined pathogenesis. It is characterized clinically by soft, painless swelling of multiple footpads that can lead to collapse of the footpad and ulceration, hemorrhage, and lameness. Histologically, the skin of the footpad is heavily infiltrated by plasma cells with variable numbers of Russell body plasma cells, neutrophils, and lymphocytes. This condition is sometimes accompanied by plasmacytic stomatitis, hypergammaglobulinemia, immune-mediated glomerulonephritis, or renal amyloidosis. A recent study indicated 50% of cases are positive for feline leukemia virus.

17.2.9.2

### NODULAR GRANULOMATOUS INFLAMMATORY DISORDERS WITHOUT MICROORGANISMS

These diseases are listed in [Box 17-14](#). The disorders in this category have traditionally been considered to be sterile because no microorganisms have been identified by microscopic examination, including with special stains for organisms, by electron microscopic examination, by cultures, or by cytologic evaluation for organisms. However, newer techniques, including the PCR that detects minute amounts of DNA, suggest the potential for microbial participation in the pathogenesis of some of these seemingly sterile inflammatory disorders, especially in human beings. It is possible, for instance, for an abnormal immune response to an as yet unidentified microbial antigen to initiate a macrophage-dominated inflammatory response. Defective down-regulation of the immune response to the organism could lead to a persistent granulomatous inflammatory process. Currently, this issue remains unresolved, but as more of these lesions are probed for microbial agents, a better understanding of these so-called “sterile” inflammatory disorders will hopefully develop.

17.2.9.2.1

#### Box 17-14 Nodular Granulomatous Inflammatory Disorders without Microorganisms

Juvenile sterile granulomatous dermatitis and lymphadenitis

Sterile pyogranuloma syndrome (idiopathic sterile granuloma and pyogranuloma)

Canine reactive histiocytosis

Idiopathic sterile nodular panniculitis

Equine generalized granulomatous disease (see Vetch Toxicosis and Vetchlike Diseases)

Feline nutritional pansteatitis (see Vitamin E Deficiency)

17.2.9.2.2

### Juvenile Sterile Granulomatous Dermatitis and Lymphadenitis (Juvenile Cellulitis, Juvenile Pyoderma, Puppy Strangles)

This disorder of unknown cause occurs in pups younger than 4 months (Fig. 17-75), with one or more of the pups of a litter developing pustular and nodular dermatitis and edema of the face, ears, and mucocutaneous junctions. The pustular and nodular lesions tend to rupture, drain, and crust. Microscopically, early lesions consist of multifocal granulomatous or pyogranulomatous perifolliculitis and dermatitis (Fig. 17-75). Early lesions are adjacent to, but do not involve, follicles; however, lesions typically progress to folliculitis, furunculosis, panniculitis, cellulitis, and granulomatous to pyogranulomatous lymphadenitis. The lesions initially are considered to be sterile, but secondary bacterial infections develop and can lead to sepsis if not treated. About half of the puppies are lethargic, and anorexia, fever, and joint pain can also occur.

17.2.9.2.3

### Idiopathic Sterile Granuloma and Pyogranuloma (Sterile Pyogranuloma Syndrome)

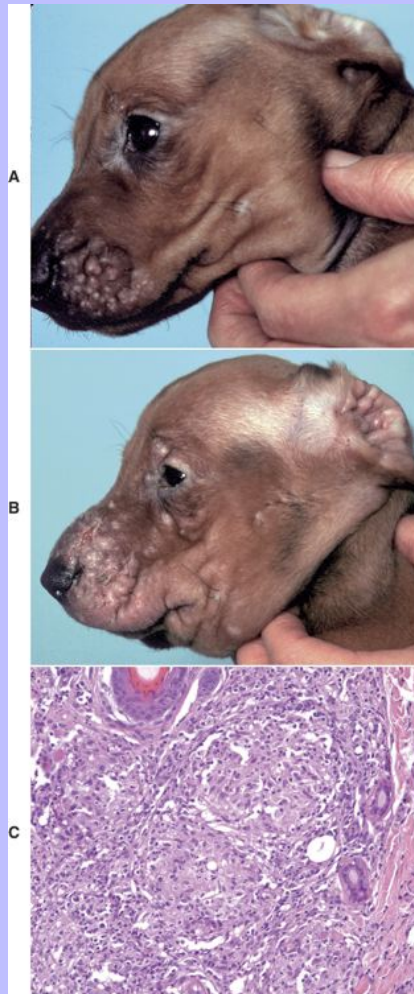

These lesions are seen most commonly in dogs and rarely cats and horses, are of unknown cause, and are characterized grossly by single or multifocal papules, plaques, or nodules most commonly in the skin of the head and extremities. Early microscopic lesions include periadnexal to coalescing nodular accumulations of leukocytes predominantly consisting of macrophages (histiocytes), neutrophils, and lymphocytes. Older lesions can efface adnexa and extend into the subcutis. Neither microorganisms nor foreign material are found microscopically, and cultures and cytology for organisms are negative. The lesions must be differentiated from those of the infectious granulomatous disorders and the reactive histiocytic disorders recognized in dogs (reactive histiocytosis).

1236

1237

Fig. 17-75 **Granulomatous dermatitis, skin, dog.** **A**, Juvenile sterile granulomatous dermatitis and lymphadenitis (juvenile pyoderma), dachshund puppy (same as in Fig. 17-75, A). The lesions, of 12 days duration, have progressed to include alopecia, thickening of the skin from edema, and crusting. The mandibular lymph node (*held between thumb and index finger*) has at least doubled in size. **C**, Note the periadnexal mixture of macrophages and fewer lymphocytes, plasma cells, and neutrophils in the dermis. No microorganisms are present. H&E stain. (**A** and **B**, Courtesy Dr. David Prieur, College of Veterinary Medicine, Washington State University. **C**, Courtesy Dr. Ann M. Hargis, DermatoDiagnostics.)

### 17.2.9.2.4 Canine Reactive Histiocytosis

Canine reactive histiocytosis is a poorly understood disorder that occurs in cutaneous and systemic forms in dogs of a variety of ages and breeds. Cultures and special stains fail to reveal causative agents, and the disorder is thought to be the result of immune dysregulation. The disorder typically has a slowly progressive, waxing and waning course but can respond favorably, as least for a time, to immunomodulatory therapy. The lesions require long-term management and often lead to death, particularly if there is systemic involvement. The cutaneous form consists of single or multifocal, nonpainful plaques or nodules composed of histiocytic cells that are immunophenotypically identified as dermal perivascular activated dendritic antigen-presenting cells (CD1<sup>+</sup>, CD4<sup>+</sup>, CD11c<sup>+</sup>, CD11b<sup>+</sup>, MHC II<sup>+</sup>, ICAM-1<sup>+</sup>, and CD90<sup>+</sup>). Also intermixed with the histiocytic cells are CD3<sup>+</sup>, CD8<sup>+</sup>, TCRαβ<sup>+</sup> T lymphocytes and CD11b<sup>+</sup> neutrophils. The systemic form is identical immunophenotypically, but can also involve the nasal mucosa, eyelids, sclera, lung, spleen, liver, bone marrow, and multiple lymph nodes in addition to the skin. Gross lesions in the cutaneous form are restricted to the skin and subcutis, can be alopecic or haired, and are most often on the head, neck, perineum, scrotum, and extremities. Histologically, there are single or multifocal infiltrates of large, round-to-oval histiocytes mixed with lymphocytes and neutrophils that, in early lesions, are periadnexal to elongate and are oriented vertically. Later the infiltrates coalesce into larger deep dermal and subcutaneous masses. Vessels are often surrounded and invaded by the infiltrates, which can result in thrombosis and infarction.

### 17.2.9.2.5 Idiopathic Sterile Nodular Panniculitis

These lesions develop in dogs, cats, and rarely horses, are of unknown cause, and are characterized grossly by single or multifocal plaques or nodules in the subcutis and occasionally deep dermis of any anatomic site. Lesions can rupture and drain, thus involve the dermis secondarily. Microscopic lesions consist of discrete, coalescing, or diffuse accumulations of macrophages (histiocytes), neutrophils, lymphocytes, and occasionally other leukocytes. The lesions must be differentiated from those of the infectious granulomatous disorders, sterile pyogranuloma syndrome, and the reactive histiocytic disorders recognized in dogs (see section on reactive histiocytosis [cutaneous and systemic histiocytosis]).

1237

1238

### 17.2.9.2.6 Xanthomas (Xanthogranulomas)

Xanthomas are rare, usually multifocal, light tan to yellow papules, plaques, or nodules located in the skin of cats and more rarely dogs and horses. The lesions take their name from the Greek “xanthos” meaning yellow. Some xanthomas are associated with abnormalities in triglyceride or cholesterol metabolism and are thus seen in animals with hereditary defects in lipid metabolism or with metabolic disorders, such as diabetes mellitus, hypothyroidism, or hyperadrenocorticism. Histologically, xanthomas associated with abnormalities in triglyceride or cholesterol metabolism consist of sheets of macrophages filled with foamy cytoplasm, scattered giant cells, and interstitial areas of granular to amorphous lipid material and cholesterol clefts. The lipids in the lesions impart a yellow to tan color to the clinical lesions, which is responsible for the name. Rarely xanthogranulomas also have developed in apparently healthy cats and dogs.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Other syndromes including equine generalized granulomatous disease (see Vetch Toxicosis and Vetch-like Diseases), and nutritional pansteatitis (see Vitamin E Deficiency) are also categorized as sterile granulomatous disorders.

### 17.2.9.3 DISORDERS OF THE CLAW BED AND LUPOID ONYCHODYSTROPHY

Onychodystrophy refers to abnormal formation of the claw (nail), onychomadesis to sloughing of claws, and paronychia to inflammation of the skin of the claw fold. These conditions are rare. Onychodystrophy and paronychia of multiple claws on multiple feet have a variety of causes including infections (e.g., bacterial, fungal), immune-mediated disorders (e.g., pemphigus, lupus erythematosus), systemic disease (e.g., hyperadrenocorticism, disseminated intravascular coagulation), and disorders of unknown cause (e.g., lupoid onychodystrophy, idiopathic onychodystrophy). Diagnosis can require amputation of the third phalanx and the adjacent skin proximal to the claw fold for histopathologic evaluation. Lupoid onychodystrophy is probably the most common cause of onychomadesis that leads to onychodystrophy of multiple claws involving multiple feet in dogs. The condition affects many breeds of dogs of varying ages; the dogs are healthy otherwise. History includes sudden loss of claws, eventually involving all claws on all feet. There is partial regrowth of misshapen, friable claws that continue to slough. Paronychia is usually absent. Histologic lesions are more prominent on the dorsal aspect of the claw and claw bed skin and include interface lymphoplasmacytic inflammation with basal cell vacuolation and apoptosis and pigmentary incontinence. Secondary bacterial infection and osteomyelitis can develop.

### 17.2.10 CUTANEOUS MANIFESTATIONS OF SYSTEMIC DISEASE

#### 17.2.10.1 LAMINITIS

The term “laminitis” refers to inflammation of the laminar structures of the hoof, but laminitis is a complex disease in which inflammation is only a part of the disease process. Laminitis can be seen in any hoofed animal, but is of greatest importance in horses and cattle. Laminitis occurs in three phases (developmental or preclinical, acute, and chronic). By definition, chronic laminitis (also called “founder”) refers to the stage of laminitis associated with radiographic or physical evidence of rotational or vertical displacement of the third phalanx relative to the hoof wall. In severe laminitis, rotation can occur as early as 24 hours after the appearance of lameness. A variety of systemic conditions cause laminitis including, but not limited to, alimentary carbohydrate overload, toxemia, and sepsis. Repeated trauma to the foot can also cause laminitis. The pathogenesis of laminitis is complex, not completely understood, and controversial. There are two basic hypotheses, vascular and toxic-metabolic, that address mechanisms responsible for the systemic causes of laminitis. The vascular hypothesis argues that digital ischemia is the primary event. The toxic-metabolic hypothesis argues that there is direct damage to epithelial cells of the laminae or to the basement membrane, and that the vascular lesions are secondary. Gross findings of the external foot in acute laminitis can be minimal. Swelling or edema of the coronary band can be seen. Extravasation of serum through the skin above the coronary band is indicative of severe laminitis. Chronic lesions are highly variable, ranging from minimal gross changes to a totally gangrenous foot. Common gross lesions include parallel circumferential hoof rings (ridges, founder rings), altered foot shape, separation of the wall from the epidermis at the coronet, depression of coronary band, flattened sole, and, in some cases, penetration of the third phalanx through the sole.

The principal clinical sign of laminitis is pain manifested as lameness, abnormal stance, or reluctance to move. Diagnosis of laminitis is based principally on clinical, radiographic, and gross findings.

## Pathologic Basis of Veterinary Disease, 4th Edition

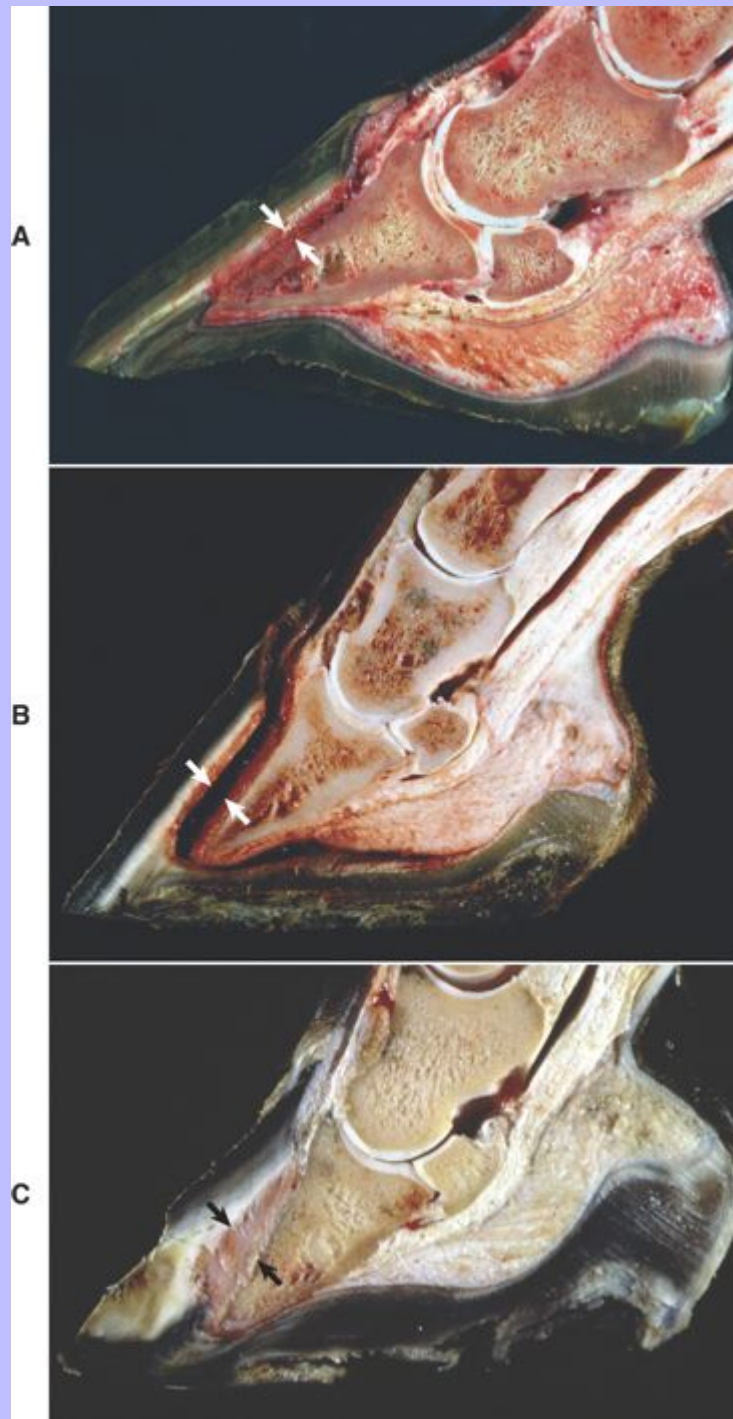

---

Histopathology is used to facilitate understanding of the pathogenesis of laminitis. Regardless of whether the initial damage is ischemic or direct injury to the epithelium or basement membrane, the lesions of acute laminitis are degeneration and necrosis of epithelial cells of the laminae, separation of epithelial cells from the basement membrane, and loss of the basement membrane. If the epithelial and basement membrane damage is minor and patchy, regeneration of the damaged cells and basement membrane occurs preserving structural integrity of the epithelial laminae and hoof, and the animal does not enter into the chronic stage of laminitis. If the epithelial and basement membrane damage is more severe and confluent, the stability created by the interdigitating epithelial laminae attaching the hoof wall to the dermis and third phalanx is disrupted and the structural integrity of the foot is weakened. In addition, the epithelial necrosis causes release of inflammatory mediators such as cytokines, which result in congestion, edema, and an influx of a small to moderate number of neutrophils and mixed mononuclear cells. The edema adds to the soft tissue swelling and, in the confines of the rigid hoof wall, further compromises digital perfusion. If the tissue damage is subtotal, remaining epithelial cells regenerate. The hyperplasia and increased cornification of epithelial cells of the primary and secondary laminae cause broadening and fusion of the laminae, which reduces the surface area of the laminae and weakens the structural support of the hoof wall. The weakened structure of the epithelial laminae and basement membrane as a result of degeneration, necrosis, and subsequent epithelial hyperplasia, combined with the weight of the animal on the hoof and pulling force of the digital flexor tendon, contribute to displacement of the third phalanx, the hallmark of chronic laminitis, and to the altered shape of the foot in chronic laminitis (Fig. 17-76). For example, the circumferential hoof rings develop because the heel growth exceeds that of the dorsal wall. The unequal growth rate of the heels compared with the dorsal wall plus the mechanical forces on the wall also lead to abnormal hoof shape such as the concave profile of the dorsal hoof, often accompanied by long under-run heels. Depression of the coronary band and flattened or dropped sole are a result of displacement of the distal phalanx relative to the hoof wall, and thus are an indication that collapse of the foot has occurred.

1238

1239

**Fig. 17-76 Laminitis, hoof, horse. A,** Normal hoof, midsagittal section. Note that the dorsal surface of the third phalanx is parallel to the epidermal laminae of the inner surface of the hoof wall (*arrows*). No space is visible at this junction or at the junction of the ventral surface of the third phalanx and the internal (weight-bearing) surface of the hoof. **B,** Acute laminitis. Note that the dorsal surface of the third phalanx has separated from the epidermal laminae of the inner surface of the hoof wall (*arrows*), leaving a large gap. The tip of the third phalanx has rotated ventrally slightly, resulting in a space between the ventral aspect of the third phalanx and the internal surface of the horny sole (weight-bearing surface of the hoof). **C,** Severe chronic laminitis. The dorsal surface of the third phalanx is widely separated from the epidermal laminae of the inner surface of the hoof wall, and the tip of the third phalanx has rotated ventrally. This space is filled with proliferated epithelium, connective tissue, and areas of inflammation (*arrows*). The shape of the entire weight bearing surface of the hoof, the external surface of the horny sole, has been altered, leading to turning up and irregular wear of the toe region and thickening of the heel of the horny sole. (**A,** Courtesy Dr. Pamela E. Ginn, College of Veterinary Medicine, University of Florida. **B,** Courtesy College of Veterinary Medicine, University of Illinois. **C,** Courtesy Dr. T. Boosinger, College of Veterinary Medicine, Auburn University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

1239

### 17.2.10.1.1 Box 17-15 Principal Cutaneous Paraneoplastic Syndromes

Paraneoplastic alopecia and internal malignancies in the cat

Exfoliative dermatitis and thymoma

Superficial necrolytic dermatitis

Pancreatic panniculitis (necrotizing panniculitis)

Nodular dermatofibrosis and renal or uterine tumors in dogs

Paraneoplastic pemphigus (see Selected Autoimmune Diseases)

### 17.2.10.2 CUTANEOUS PARANEOPLASTIC SYNDROMES

Cutaneous paraneoplastic syndromes are rare dermatoses that occur in association with internal malignancies (Box 17-15). Confirmation of a dermatosis as a paraneoplastic syndrome requires strict adherence to established clinical, histopathologic, and in some instances, immunologic criteria. Conditions meeting these criteria currently recognized in animals include paraneoplastic pemphigus (discussed in the section on autoimmune diseases); paraneoplastic alopecia and internal malignancies in the cat; exfoliative dermatitis and thymoma in the cat, dog, and rabbit; and superficial necrolytic dermatopathy in the dog and cat. Dermatofibrosis in the dog, pancreatic panniculitis, and multisystemic eosinophilic epitheliotropic disease in the horse have also been associated with underlying neoplasia; however, they have not yet been proven to be true paraneoplastic syndromes. This list is exclusive of the endocrine dermatoses associated with functional tumors of endocrine organs. Many other syndromes are documented in human beings, and it is likely more will be documented in animals in the future. The refractory nature of these syndromes and their significance as an indicator of systemic disease underscores the importance of their recognition.

#### 17.2.10.2.1 Paraneoplastic Alopecia Associated with Internal Malignancies in the Cat (Pancreatic Paraneoplastic Syndrome)

This syndrome is a rapidly progressive, largely ventrally distributed, symmetric alopecia that develops in older cats with metastatic pancreatic or biliary carcinomas. The pathogenesis of this condition is not known. The alopecia typically affects the ventrum, legs, and footpads. The ears and periocular skin are less frequently involved. Alopecic skin is smooth, soft, and often has a shiny or glistening appearance. Histologically, affected skin has small inactive hair follicles with a reduction or absence of the stratum corneum. Some cats groom excessively, and it has been suggested that the smooth shiny appearance of the skin is because of the absence of the stratum corneum. In other areas of the skin there is variable orthokeratotic and parakeratotic hyperkeratosis in which *Malassezia pachydermatis* is sometimes identified. In addition to the alopecia, the cats have systemic signs of anorexia, weight loss, and lethargy.

#### 17.2.10.2.2 Exfoliative Dermatitis and Thymoma

A generalized exfoliative dermatitis has been documented as a paraneoplastic syndrome of older cats with thymomas. More recently, the condition has been recognized in dogs and rabbits. Immune dysregulation probably plays a role in lesion development. Gross lesions begin as scaling and erythema

## Pathologic Basis of Veterinary Disease, 4th Edition

---

of the head and ears and progress to generalized alopecia with scales, crusts, and ulcers. Histologically, the lesions include basal cell hydropic degeneration, lymphocyte exocytosis, and lymphocyte clustering around apoptotic keratinocytes of the epidermis and outer follicular root sheath. The lesions are compatible with the diagnosis of erythema multiforme or a graft-versus-host-type reaction. Cats with this syndrome often have clinical signs referable to an intrathoracic mass resulting in dyspnea.

### 17.2.10.2.3 Superficial Necrolytic Dermatitis (Diabetic Dermatopathy, Hepatocutaneous Syndrome, Necrolytic Migratory Erythema, Metabolic Epidermal Necrosis)

This is an uncommon disorder reported primarily in older dogs with deranged nutrient metabolism because of diabetes mellitus, hepatic dysfunction, or less commonly with glucagon-secreting pancreatic islet tumors. Anticonvulsant therapy has also preceded the development of superficial necrolytic dermatitis, but it is uncertain if anticonvulsant therapy causes the disease or possibly exacerbates subclinical disease. The disorder is rarely seen in cats; one cat with superficial necrolytic dermatitis had concurrent pancreatic endocrine carcinoma. The pathogenesis of superficial necrolytic dermatitis is not completely understood, and may vary with the underlying defect. When glucagon is elevated, persistent gluconeogenesis is thought to result in a negative nitrogen balance with protein degradation, including proteins in the epidermis. However, when glucagon is not elevated, as occurs in human beings with some types of hepatic or malabsorptive disease and in dogs with diabetes and multinodular vacuolar hepatopathy, it is thought that deficiencies of certain essential fatty acids, zinc, and amino acids play a role. Clinical lesions of scaling, crusting, erythema, and alopecia develop on the face, distal extremities, and genitalia. Footpad lesions consist of crusting and fissuring or ulceration (Fig. 17-11), and result in lameness. Microscopic lesions, when fully developed, are considered diagnostic and consist of trilaminar thickening of the epidermis in which the stratum corneum has marked parakeratosis, the upper stratum spinosum is pale with reticular degeneration, and the lower spinous and basal cell layers are hyperplastic (Fig. 17-11). Secondary infections with bacteria or yeast frequently complicate lesions, and secondary infection with dermatophytes also has been seen.

1240

1241

### 17.2.10.2.4 Pancreatic Panniculitis (Necrotizing Panniculitis)

Pancreatic panniculitis is an acute rare disorder that has developed in dogs with pancreatic neoplasia and pancreatitis. The lesions are thought to be a result of the release of pancreatic enzymes (e.g., lipases) either from damaged pancreatic exocrine cells or from neoplastic exocrine cells. The lipases enter the systemic circulation and subsequently locate in the panniculus. Gross lesions consist of multiple, frequently ulcerated and hemorrhagic nodules within the subcutis. Histologically there is necrosis of adipose tissue (caused by the lipases) with fine basophilic granularity (caused by mineralization of the necrotic fatty tissue). Neutrophilic inflammation occurs at the periphery of the necrotic foci.

### 17.2.10.2.5 Nodular Dermatofibrosis and Renal Disease in the Dog

In nodular dermatofibrosis, multiple cutaneous nodules composed of excessive collagen coexist with renal cystadenomas, cystadenocarcinomas, hyperplastic epithelial cysts, or uterine smooth muscle tumors. Renal lesions are often bilateral and may not be detectable clinically for months or years after the appearance of the cutaneous nodules. The syndrome has been described in the German shepherd, boxer, golden retriever, and mixed-breed dogs, and is thought have an autosomal dominant mode of inheritance in the German shepherd. Whether the condition is a true paraneoplastic syndrome with the renal neoplasm inducing dermal fibrosis or the simultaneous occurrence of two independent conditions

## Pathologic Basis of Veterinary Disease, 4th Edition

---

with a common hereditary linkage is undetermined. Gross lesions consist of firm dermal and subcutaneous nodules on legs, head or ears. Histologic lesions consist of nodular dermal and subcutaneous aggregates of poorly cellular, mature dermal collagen bundles that are slightly thickened. In the dermis, the collagen bundles blend often imperceptibly with bordering collagen, but in the subcutis, the nodules are usually circumscribed. Adnexa are normal or hyperplastic. The cutaneous nodules are benign but serve as a marker for the more serious renal lesions.

### 17.2.10.2.6 Paraneoplastic Pemphigus

See Selected Autoimmune Reactions, Paraneoplastic Pemphigus.

### 17.2.11 CUTANEOUS NEOPLASIA

The skin is a common site of neoplastic growth in most animals; the neoplasms are of ectodermal, mesodermal, and melanocytic origin (Box 17-16). Ectodermal neoplasms of the epidermis and adnexa are most often benign with the exception of the neoplasms of the apocrine sweat glands, apocrine glands of the anal sac, and neoplasms of the surface epithelium (squamous cell carcinomas).

Benign neoplasms do not metastasize or invade adjacent tissue. In general, benign neoplasms are circumscribed, grow by expansion, and are composed of well-differentiated cells that closely resemble the cells or tissue of origin (Box 17-16). Malignant neoplasms are locally invasive and often metastasize. They are more often composed of anaplastic cells with a high mitotic index that no longer resemble the cells of origin. Anaplastic cells are pleomorphic (vary in cell size and shape) and have a large, vesicular nucleus with increased size and number of nucleoli (Box 17-16). Malignant cells develop surface alterations such as altered antigenicity, decreased numbers or altered location of receptors for adjacent cells, and increased receptors for components of the extracellular matrix. Changes such as these allow malignant cells to detach from the primary site of tumor growth, move through tissues, and in some cases escape detection by the host's immune system. A specific example is the loss of E-cadherins (proteins responsible for epithelial cell to cell attachment) by some types of carcinomas. E-cadherins are partially responsible for the "contact inhibition" that leads to density control and inhibits uncontrolled proliferation of epithelial cells.

Neoplasms of the skin develop secondary to the same basic molecular changes, leading to the development of neoplasms of any tissue. The neoplastic transformation of a cell is the end result of a series of events causing damage to the cellular DNA. Most agents that are known to be carcinogenic target and damage DNA. Solar radiation, x-radiation, viral infections, and continued trauma are important contributors to neoplastic transformation of components of the skin. Continued trauma contributes to tumor development by increasing cell turnover, which in turn increases the chance of mutations. Not all factors contributing to the development of cutaneous neoplasms are known.

Four categories of genes encode for a large number of proteins responsible for regulation of cellular proliferation and differentiation. These categories are the tumor suppressor genes, the protooncogenes, genes that regulate apoptosis, and genes that regulate DNA repair. Damage to these genes results in deranged cellular proliferation by the abnormal expression or function of proteins such as growth factors, growth factor receptors, signal-transducing proteins, cell cycle regulators, and nuclear transcription factors. The majority of malignant neoplasms have evidence of damage (mutation) of multiple genes within these categories. Mutations are often collected by cells in a stepwise manner that imparts increasing degrees of malignant potential. These molecular changes are known to correlate with morphologic changes and the clinical behavior of some neoplasms. For example, it is known that squamous cell carcinomas often develop in a stepwise

1241

1259

## Pathologic Basis of Veterinary Disease, 4th Edition

manner and progress through several recognizable stages: hyperplasia (increased number of cells; no cellular atypia or tissue disorganization) → dysplasia (increased mitoses, cellular atypia, and tissue disorganization consisting of loss of polarity) → carcinoma in situ (increased tissue disorganization, mitoses, anaplastic nuclei, but no invasion of underlying basement membrane) → invasive squamous cell carcinoma (disruption of the basement membrane with dermal invasion by anaplastic carcinoma cells).

### 17.2.11.1 Box 17-16 Examples of Tumors of the Skin

#### 17.2.11.1.1 ECTODERMAL TUMORS

**Basal cell tumor, skin, upper eyelid and dorsal to eye, cat.** The tumor is circumscribed, raised, and sparsely haired. The tumor and bordering skin can be easily moved from side to side above the deeper tissue because the tumor has not invaded into underlying tissue.\*

**Basal cell tumor of epidermal origin, skin, cat.** The dermis is expanded by multiple lobules of neoplastic basal epithelial cells. The centers of some of the lobules have cystic degeneration and contain pigmented debris. Basal cell tumors arise from basal cells of the epidermis and those of hair follicles. H&E stain.

**Trichoblastoma (basal cell tumor of follicular origin), skin, dog.** Note ribbon (medusoid) pattern produced by the proliferating basal cells. This pattern is one of several patterns (ribbon, trabecular, granular cell, spindle cell) typical of basal cell tumors of follicular origin, also called trichoblastomas. H&E stain.†

#### 17.2.11.1.1 Infundibular Keratinizing Acanthoma

**Infundibular keratinizing acanthoma (intracutaneous cornifying epithelioma, keratoacanthoma), skin, dog.** Note horny growth (cutaneous horn) projecting from surface of the tumor. Cutaneous horns can arise from a variety of benign or malignant epidermal lesions (actinic keratosis; Fig. 17-40, B, squamous cell carcinoma) or adnexal lesions, especially infundibular keratinizing acanthomas.\*

**Infundibular keratinizing acanthoma, skin, dog.** Note the circumscribed tumor located in the dermis and subcutis. The tumor consists of irregularly sized lobules of stratified squamous cornifying epithelium supported by a small quantity of collagenous stroma. The tumor is often "cystic" and contains laminations of stratum corneum, which can extend through the epidermal surface and form a "cutaneous horn." The epithelium forming the lobules of the tumor blends with the overlying epidermis. H&E stain.†

**Infundibular keratinizing acanthoma, skin, dog.** Higher magnification of wall of the tumor. The lobules border concentric laminations of stratum corneum and are supported by scant mucinous stroma. These tumors resemble squamous cell carcinoma but have a circumscribed, noninvasive border. H&E stain.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.11.1.1.2 Sebaceous Gland Adenoma

**Sebaceous gland adenoma, skin, dog.** This common tumor of sebaceous glands often protrudes above the epidermal surface. The tumors are hairless and greasy because of sebaceous gland secretion.

**Sebaceous gland adenoma, skin, dog.** Lobules of well-differentiated sebaceous glands are present in the dermis and cause polypoid elevation of the overlying epidermis. A duct with sebaceous secretion is also present. Ducts connect via follicular epithelium to the epidermis providing the sebaceous (greasy) secretion to the surface. H&E stain.

**Sebaceous gland adenoma, skin, dog.** Note the close resemblance of the lobules of tumor cells to those of nonneoplastic sebaceous glands, a feature suggesting benign behavior.

### 17.2.11.1.1.3 Squamous Cell Carcinoma

**Squamous cell carcinomas, skin, abdomen, dog.** Note multiple ulcerated squamous cell carcinomas in nonpigmented, sparsely haired abdominal skin. These are solar induced squamous cell carcinomas that developed in a beagle dog living outdoors at a high altitude region where the level of UV light is increased.

**Squamous cell carcinoma, skin, dog.** The dermis is invaded by neoplastic squamous epithelial cells that have arisen from the basal cells of the epidermis (*above center*) and that have differentiated to form irregular islands of squamous epithelium. H&E stain.\*

**Squamous cell carcinoma, skin, dog.** Islands of neoplastic epithelial cells with squamous differentiation have invaded the dermis and are surrounded by proliferating fibroblasts and collagen (desmoplasia). H&E stain.

### 17.2.11.1.2 MESODERMAL TUMORS

#### 17.2.11.1.2.1 Cutaneous Histiocytoma

**Cutaneous histiocytoma, skin, nose, dog.** Circular raised alopecic tan nodule is present. Cutaneous histiocytomas frequently spontaneously regress. *Inset:* section of cutaneous histiocytoma illustrating the non encapsulated, solid dermal mass protruding above the epidermal surface.

**Histiocytoma, skin, dog.** The histiocytoma elevates the epidermal surface, and consists of a solid mass of histiocytic cells. H&E stain.\*

**Histiocytoma, skin, dog.** Note the polyhedral to round cells in the dermis and the down-growth of epidermis (rete ridges) into the histiocytoma (a common feature of these tumors). *Inset:* Higher magnification of the histiocytic cells. H&E stain.\*

## 17.2.11.1.2.2 Cutaneous Lymphoma

**Cutaneous lymphoma, skin, neck and lateral thorax, horse.** Note the nodules that are masses of neoplastic lymphocytes and infiltrating nonneoplastic lymphocytes in the dermis, causing elevation of overlying epidermis.<sup>†</sup>

**Cutaneous lymphoma, skin, horse.** Sheets of neoplastic lymphocytes and infiltrating nonneoplastic lymphocytes have obliterated the normal dermal architecture except for a arrector pili muscle (*center*). The overlying epidermis is normal. H&E stain.

**Cutaneous lymphoma, skin, horse.** Note the population of different appearing lymphoid cells. Some resemble normal lymphocytes and are small and well differentiated, whereas others are large and pleomorphic with vesicular nuclei and prominent nucleoli. Immunohisto-chemical and genetic studies of many cases of cutaneous lymphoma in the horse have demonstrated that the small well-differentiated lymphocytes are nonneoplastic T lymphocytes, whereas the large pleomorphic lymphocytes are neoplastic B lymphocytes. It is speculated that the neoplastic B lymphocytes produce cytokines that lead to infiltrates of nonneoplastic T lymphocytes and sometimes other leukocytes. Cutaneous lymphoma in the horse with this morphology and immunophenotype is referred to as a T-lymphocyte rich B-lymphocyte lymphoma subtype. H&E stain.

## 17.2.11.1.2.3 Epitheliotropic Lymphoma

**Epitheliotropic lymphoma, skin of lip and oral mucosa, dog.** Note swelling, erythema, and depigmentation. Lymphocytes invade the epithelium and can cause depigmentation by displacing and damaging pigment containing epithelial cells and resident melanocytes of the basal region of the epidermis. Because of the involvement of the oral mucosa and mucocutaneous junctions and the presence of depigmentation and sometimes erosions, epitheliotropic lymphoma can be clinically confused with immune-mediated diseases such as systemic lupus erythematosus.

**Epitheliotropic lymphoma, skin, dog.** Neoplastic lymphocytes are located predominantly in the lower layers of the epidermis. *Inset:* Higher magnification of the neoplastic lymphocytes in the epidermis. Some of the lymphocytes are clustered together, forming microabscesses (Pautrier's microabscesses) (arrow). H&E stain.\*

**Epitheliotropic lymphoma, skin, dog.** Neoplastic lymphocytes are located predominantly in the lower layers of the epidermis and are labeled for CD3, indicating that they are T lymphocytes. *Inset:* Higher magnification of the malignant lymphocytes in the epidermis. Immunohisto-chemical stain for CD3+ lymphocytes.

## 17.2.11.1.2.4 Mast Cell Tumor

**Mast cell tumor, skin, ventral thorax, dog.** Note the irregular nodular and erythematous masses. Mast cell tumors in dogs can clinically resemble areas of inflammation because mast cells can degranulate and release inflammatory mediators (e.g., histamine, factors chemotactic for eosinophils and neutrophils, prostaglandins, serine esterases, and tumor necrosis factor- $\alpha$ ) causing the inflammatory response.\*

**Mast cell tumor, skin, dog.** The dermis is infiltrated by well-differentiated neoplastic mast cells with abundant gray to blue, finely granular cytoplasm and centrally located nuclei. H&E stain. *Inset:* Mast cells stained to illustrate metachromatic granules. In some cases, it can be difficult to differentiate round cell tumors such as histiocytomas, lymphomas, and mast cell tumors from each other. Demonstration of metachromatic cytoplasmic granules is an indicator of the presence of mast cells. *Metachromasia* means that the tissue or cellular component stains a color different from that of the staining dye because of a chemical reaction between the dye and the tissue component. For example, mast cell granules stain purple with the blue dye, toluidine blue. Toluidine blue stain.†

**Mast cell tumor, skin, dog.** Mast cell tumor with degranulated eosinophils that border a collagen fiber. The collagen fibers and bordering eosinophilic material have been referred to as "flame figures" due in part to their irregular, sometimes radiating, edges and brightly eosinophilic staining intensity. H&E stain.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.11.1.2.5 Fibrosarcoma

**Fibrosarcoma, skin, leg, cat.** The tumor has enlarged to such a degree that it has caused ulceration of the epidermis. Fibrosarcomas are locally invasive and difficult to excise completely. Amputation is an option for fibrosarcomas located on distal extremities.

**Fibrosarcoma, skin, cat.** Cells of the fibrosarcoma (*arrows*) have infiltrated between skeletal muscle fibers (*arrowheads*). H&E stain.

**Fibrosarcoma, skin, cat.** Note haphazardly arranged intersecting bundles of anaplastic spindle shaped neoplastic cells within a collagenous stroma. Anaplastic cells are pleomorphic in that they vary in cell size and shape and have a large, vesicular nucleus with increased size and number of nucleoli. Numerous mitotic figures are also present (*arrows*). H&E stain.<sup>†</sup>

### 17.2.11.1.2.6 Hemangioma

**Hemangioma, skin, hind leg, dog.** Note raised red to dark red circumscribed mass in nonpigmented and sparsely haired skin.

**Hemangioma, skin, dog.** Well-defined mass of proliferative, blood-filled, vascular channels in the dermis has elevated the epidermis. H&E stain.

**Hemangioma, skin, dog.** The dermis is expanded by a circumscribed mass of blood filled vascular channels lined by well-differentiated endothelial cells. Note flattened well-differentiated endothelial cells (*arrows*) that form a single uniform layer. H&E stain.<sup>†</sup>

### 17.2.11.1.2.7 Hemangiosarcomas

**Hemangiosarcoma, skin, dog.** Note multiple raised red masses in nonpigmented and sparsely haired skin of whippet.

**Hemangiosarcoma, skin, dog.** Note poorly demarcated margin between tumor (*mostly on the right*) and normal tissue (*mostly on the left*). H&E stain.

**Hemangiosarcoma, skin, dog.** The dermis is effaced by highly irregular vascular channels lined by plump, hyperchromatic endothelial cells with numerous mitotic figures (*arrows*). H&E stain.<sup>†</sup>

## Pathologic Basis of Veterinary Disease, 4th Edition

### 17.2.11.1.3 MELANOCYTIC TUMORS

#### 17.2.11.1.3.1 Melanoma

**Melanocytoma, skin, dog.**  
Note raised pigmented brown to black hairless mass.\*

**Melanocytoma, skin, dog.** The dermis is diffusely infiltrated by sheets of variably pigmented melanocytes, which have prominent nucleoli and moderate variation in the size of cells and nuclei. H&E stain.†

**Melanoma, skin, dog.** Note clusters of pigmented melanocytes within the epidermis. This is called "junctional activity" and is a feature of melanocytic tumors. H&E stain.

# Pathologic Basis of Veterinary Disease, 4th Edition

Table 17-13 Selected Cutaneous Neoplastic and Neoplastic-like Lesions of Domestic Animals

Lesion	Cause	Species Age, Breed, Sex	Location	Gross Pathology	Histopathology	Biologic Behavior	Unique Features
Cutaneous papilloma (wart) (verruca) (Fig. 17-46)	Often caused by papillomavirus	Common in horses, cattle	Horse: about the nose, lips, inner aspect of ears (aural plaques)	Flattened to papillary mass, single or multiple, on narrow or broad base	Papillary projections of epithelium over collagen core	Most benign and will regress	May have viral inclusion bodies
		Infrequent in dogs, goats, sheep	Any location, often the head	Inverted variety occurs	Epithelium thickened by hyperkeratosis and acanthosis	Occasional transformation to squamous cell carcinoma	May have koilocytes (keratinocytes with swollen clear or gray cytoplasm)
		Rare in cats					
		Often young age					
Fibroepithelial polyp (skin tag)		Congenital in foals	Any location	Raised smooth polyp	Epidermis covering collagen core	Benign	More collagen than squamous papilloma
		Dogs					Location
Fibropapilloma (also see sarcoid)	Bovine papilloma virus 2	Young bulls, cows	Glans penis of bulls	Irregular mass attached to glans penis, less papillary than cutaneous papilloma	Proliferative epithelium and whorls and fascicles of fibroblasts and collagen	Look aggressive histologically and may recur after excision, but do not metastasize	Viral cause
			Vulva and vagina cows				
Cutaneous cysts (Table 17-5, cyst)	Follicular and apocrine (occluded follicles or ducts)	Any species, often dogs and cats	Anywhere on skin	Cyst filled with soft, tan, greasy stratum corneum and sebum (follicular and sebaceous); hair (dermoid); or clear fluid (apocrine and ciliated)	Cystic structure with the wall composed of epidermal or adnexal epithelium	Nonneoplastic	Rupture and foreign body inflammation may develop
Follicular			Dermoid: dorsal midline of Rhodesian ridgeback				
Sebaceous duct	Dermoid (genetic)						
Dermoid	Ciliated (developmental anomaly)		Ciliated: neck of cats		Ciliated: from thyroglossal duct or respiratory epithelium		
Apocrine							
Ciliated							
Cutaneous horn (Box 17-16)	Associated with benign or malignant epithelial tumors	All domestic species	Any location	Hard conical hornlike growth	Horn consists of laminations of compact stratum corneum	Both neoplastic and nonneoplastic varieties	Gross appearance
			Footpads of cats	Greater height than diameter			
	FelV cat footpads		Areas of		Base may be a hyperplastic, neoplastic, or inflammatory lesion	Depends on nature of underlying lesion	
	Dermatophilus associated		Dermatophilus infection in ruminants				
	Papillomavirus						
Hair follicle tumors	Genetic (breed predilections)	Dogs, occasionally cats	Any location	Firm and discrete tumors	Variable depending on tumor	Most tumors of follicular origin are benign	May mineralize
Trichoepithelioma				Some cystic			
Tricholemmoma	May be multicentric in predisposed breeds	Pilomatricoma Kerry blue terrier		Some ulcerate	Resemble portion of follicle from which they arise	Malignant varieties of trichoepithelioma	May result in foreign body response if cystic tumor ruptures
Pilomatricoma		Trichoepithelioma Basset hound		Some mineralize		and pilomatricoma have been described	
Trichoblastoma (hair follicle tumor of basal cells)							
Infundibular keratinizing acanthoma (intracutaneous cornifying epithelioma) (Box 17-16)	Genetic (breed predilection)	Norwegian elkhound, may be multicentric	Often back and tail when multicentric	Dermal or subcutaneous mass, often with pore opening onto skin surface	Invaginated cyst with wall composed of lobules of stratified squamous epithelium	Benign	Resembles squamous cell carcinoma histologically
				May be covered with cutaneous horn			
Malignant trichoepithelioma (matrical carcinoma)	Unknown	Dogs	Any location in skin	Large, dermal or subcutaneous mass	Not usually connected with epidermis	Malignant variety	Matrical keratinization
				Poorly circumscribed, invade subcutis	Similar to benign, but greater nuclear pleomorphism and mitotic activity	Trichoepithelioma: frequent metastasis to lymph nodes or lungs; recurrence also reported	Pilomatricoma has no trichohyalin granules; often has calcification or ossification
Malignant pilomatricoma						Pilomatricoma: may metastasize	

# Pathologic Basis of Veterinary Disease, 4th Edition

Benign basal cell tumor* (Box 17-16)	Unknown	Benign basal cell tumor of epidermal origin (cats)	Often head, neck, and cranial trunk	Generally solitary, firm nodules or plaques, which may ulcerate	Benign: resemble basal cells	Benign	Lack intercellular bridges
Basal cell carcinoma		Carcinoma (dogs and cats)		Carcinoma: may be multicentric	Carcinoma: ragged margins; solid, clear cell; and keratinizing types	Carcinoma locally aggressive with low potential for metastasis	May contain melanin pigment and can be confused with melanoma
		Rare in other domestic animals					May be contiguous with epidermis
Squamous cell carcinoma (Box 17-16) (in situ)	Solar radiation	All species, especially white cats,	Nonpigmented or lightly pigmented and sparsely haired skin	Variable: nodular, proliferative, crusty, ulcerative	Cords and islands of squamous cells	May recur	Keratin pearls, intercellular bridges
Bowen's-like disease in cats develops in haired, often pigmented skin, multicentrically)	Trauma	Hereford cattle, light-colored horses, white or partly white dogs	Nail bed (dogs, cats)	Cutaneous horn may be present	Keratin pearls	Metastasis to lymph nodes and beyond may develop	Spindle-cell and pseudoglandular varieties occur
	Carcinogens		Penis/prepuce (horses)		Dyskeratosis		
	Papillomavirus in Bowen's-like disease	Less in pigs			Intercellular bridges	Those of equine penis and feline nail bed are more aggressive	
	Some unknown	Adults to aged			Basement membrane disrupted		
						Solar-associated are slow to metastasize	
Claw bed tumors	Unknown	Dogs: largebreed, blackhaired, predisposed to multiple squamous cell carcinomas	Claw bed	Variable	Depends on type of lesion or tumor	Malignant	Differentiate from melanoma of dogs
Inclusion cyst	Trauma		May be multiple	Swelling of claw bed			pulmonary and squamous cell carcinoma in cat, which may metastasize to multiple digits
Papilloma				Loss of claw			
Keratoacanthoma		Cats		Deformed claw			
Squamous cell carcinoma							
Melanoma							
Apocrine adenoma: simple, complex, mixed, and ductal	Unknown	Older dogs and cats	Any location glands present	Adenoma: small, slow growing, cystic, circumscribed	Benign: variable appearance, resemble glandular or ductal epithelium	Adenomas: benign	Carcinomas may resemble exudative dermatitis
Apocrine adenocarcinoma: simple, complex, mixed, and ductal			Older female dogs: bilateral adenocarcinomas may develop from apocrine glands of anal sacs	Carcinomas: firm, infiltrative	Mixed type have myoepithelium, cartilage, or bone	Carcinomas: aggressive, may metastasize early	Anal sac carcinomas are often associated with hypercalcemia
						Carcinomas of anal sac usually solid	
Sebaceous gland adenoma (Box 17-16)	Unknown	Adenoma common in adult dogs:	Head, neck, anywhere	Adenoma: gray-tan, greasy, lobulated, raised	Adenoma: similar to sebaceous gland	Adenomas: benign	Eyelid meibomian gland tumors are similar
Sebaceous gland epithelioma		Cocker spaniel, poodle		Epithelioma: discrete, firm; may ulcerate	Epithelioma: more basal cells and mitoses	Epitheliomas may recur	Nodular hyperplastic lesions of sebaceous glands also very common
Sebaceous gland carcinoma		Less common in cats		Carcinoma: often ulcerated	Carcinoma: less fat in cells, less differentiated	Carcinomas: locally invasive; rarely metastasize	
		Rare in other animals					
Perianal gland adenoma (hepatoid gland adenoma)	Hormonal influence	Older dogs	Skin near anus, base of tail, prepuce, vulva; less elsewhere	One or more raised nodules often ulcerated, circumscribed, orangish tan and greasy on cut surface	Adenoma: similar to perianal gland	Most are adenomas, which are benign	Location and hormonal sensitivity
Perianal gland epithelioma		Intact males predisposed			Epithelioma: more basal cells and mitoses	In males, castration or estrogen therapy may cause regression of adenomas	
Perianal gland carcinoma					Carcinoma: infiltrative, less differentiated, and more mitoses		
						Carcinomas: low grade malignancy	

# Pathologic Basis of Veterinary Disease, 4th Edition

Canine cutaneous histiocytoma (Box 17-16)	Unknown  Langerhans' cell of origin (epidermal dendritic antigen-presenting cell)	Dogs; more than half of the tumors develop before 2 years of age  Purebred dogs predisposed	Head, especially pinna; distal forelegs; and feet	Usually single  Dome-shaped  Circumscribed  Often ulcerated	Sheets of large round cells (histiocytes) replace adnexa and collagen  Frequent mitoses  Later necrosis and lymphocytic inflammation	Rapid growth followed by regression  Rarely recur  No metastasis	Young dogs  Rapid growth  Regression
Canine reactive histiocytosis (cutaneous and systemic)	Unknown Activated, dermal, perivascular antigen-presenting cell (dendritic cell) origin	Adult dogs Systemic: Bernese mountain dogs and a few other breeds	Cutaneous: multiple cutaneous sites  Systemic: skin and other organs	Multiple cutaneous and subcutaneous plaques and nodules ± systemic lesions	Histiocytic cells and variable mix of lymphocytes, plasma cells, and neutrophils	Remissions, relapses Prolonged course Slowly progressive	Recurrent  May have nasal lesion or systemic involvement
Histiocytic sarcoma (disseminated) (also known as malignant histiocytosis)	Unknown  Nonactivated, dendritic cell (antigen presenting cell) origin	Bernese mountain dog  Retriever (golden, Labrador)  Rottweiler, others	Skin and subcutis are rarely affected  Multisystemic involvement	Multinodular, invasive, destructive	Anaplastic, large, round and/or plump spindle cells, other leukocytes	Aggressive  Usually fatal disease	Breed predisposition  Multisystemic masses  Anaplastic cell populations
Cutaneous lymphoma (Box 17-16)	Unknown	Dogs; less common in cats and horses  Age variable	Skin or oral  Dermis or epidermis	Variable  1. Red scaly skin  2. Mucocutaneous ulceration/depigmentation  3. Single/multiple cutaneous masses  4. Infiltrative and ulcerative mucosal epithelium ± systemic lesions	Dermal: sheets of lymphocytes in dermis  Epidermal: lymphocytes in epidermis and adnexal epithelium  Angiocentric: lymphohistiocytic dermal masses with angiocentric pattern	Ultimately terminate fatally  Lymphomatoid granulomatosis is aggressive, has angiocentric pattern, and may invade vessels and cause infarction	Epidermal form may mimic dermatitis, autoimmune disease, or stomatitis  Equine lymphosarcoma is pleocellular and can be confused with inflammation
Merkel cell tumor	Neuroendocrine origin	Dog, rare tumor	Skin or oral	Nodular mass	Nests of round cells with collagen septa	Usually benign	200-nm granules seen ultrastructurally Cytoplasmic immunoglobulin present
Cutaneous plasmacytoma (extramedullary plasmacytoma)	Unknown	Dog, rarely cat  Aged adult  Both sexes	Ear, lip, digit, and other mucocutaneous and cutaneous sites	Usually solitary, raised, reddish discrete, nodule	Densely cellular; single or multiple variably sized nuclei; many mitoses  Resemble plasma cells; may have amyloid	Usually do not recur  Subcutaneous or those with amyloid may be aggressive and recurrent  Rare association with multiple myeloma	May have amyloid deposits
Mast cell tumor (mastocytoma) (Box 17-16)	Unknown  Genetic influence  In cats, FIV associated	Common tumor of dogs, especially boxers, less common in other species  Siamese cats have histiocytic variety  Generally adults, less common in neonates	Dog: often legs, trunk  Feline: head	Solitary or multiple nodules  Poorly circumscribed edematous swellings  May ulcerate early	Sheets of large round cells with bluish granular cytoplasm  Not encapsulated  Many eosinophils, in dogs especially  Vasculitis  Collagen degeneration	Canine: behavior may correspond to histologic grade  May disseminate  Feline histiocytic type may spontaneously regress  Equine generally benign	Metachromatic granules, eosinophils  Other lesions: vasculitis, collagen degeneration, gastrointestinal ulceration  Prolonged coagulation time

# Pathologic Basis of Veterinary Disease, 4th Edition

Melanoma: benign (melanocytoma)	Genetic factors	Common: dogs and horses, and some strains of pigs and angora goats	Dog: head, eyelids, legs, digits	Dog and cats: single	Epithelioid to spindle-shaped cells containing variable quantity of pigment	Canine: oral, mucocutaneous, subungual, often malignant; haired skin often benign	Melanin pigment in cytoplasm
junctional dermal compound (Box 17-16)	Unknown		Horse: perineal skin and underside of root of tail	Horse: multiple			Common in horses that fade to gray
Malignant melanoma	Ultraviolet light	Uncommon: cats			Nests of these cells bordered by thin collagen septa	Gray horses: usually progressive and multicentric	
	Angora goats	Rare: other species	Feline: head	Usually dark brown or black	Malignant; are anaplastic and may be amelanotic	Location, size, mitotic index, and cell morphology help predict behavior	
Fibroma	Fibrosarcoma:	Adult to aged	Head, legs, and sites of vaccination in cats	Circumscribed (fibroma)	Interlacing bundles of fibroblasts and collagen	Fibromas: benign	Fibrosarcomas in cats have been caused by FeLV
Fibrosarcoma (Box 17-16)	1. FeLV and FeSV are associated with development of multiple sarcomas in young cats	All domestic animals		Firm to soft		Fibrosarcomas are infiltrative and often recur, but metastasis is uncommon	plus FeSV, and by vaccination
	2. Vaccination in cats	Fibrosarcomas: common in cats, less common in dogs, rare in other species		Resilient	Fibrosarcoma may have multinucleated giant cells		
Equine sarcoid	Bovine	Most common skin tumor of horses	Skin of legs, head, ventral trunk	Types: verrucous fibroblastic flat or occult mixed	Fibroblastic proliferation with pseudoepitheliomatous hyperplasia	Locally invasive	Autotransplantable
Feline sarcoid (Fig. 17-47)	papilloma-virus/equine	Donkey, mule				Frequently recur	Rare spontaneous regression
Myxoma	Probable papilloma-virus/feline	Cat				Do not metastasize	
Myxosarcoma	Unknown	Rare in domestic animals	Any location, often limbs	Poorly defined and infiltrative, soft and mucoid	Fusiform and stellate cells within mucinous matrix	Infiltrative	Some consider myxomas (sarcomas) to be a type of fibroma (sarcoma)
		Adult to aged		Gelatinous		Recur frequently	
Hemangiopericytoma (cell of origin is controversial, probably pericyte or possibly neural)	Unknown	Dogs	Dermis and subcutis of extremities	Gray to pink	Concentric laminations of spindle cells	Often recur	Concentric laminations of spindle cells around vessels
Some consider this to be a malignant peripheral nerve sheath tumor		Adult to aged		Lobulated		Locally invasive	
		More in females		Firm and nodular or more gelatinous		Rarely metastasize	
Nerve sheath tumors	Unknown	Cats, very rare					
Neurofibroma		Dogs, less others	Cutaneous tumors are uncommon, more common on head of cats, legs of dogs, and eyelids of horses	Nodular	Bundles, whorls, and palisades of spindle cells	Dogs and cats: locally invasive, may recur	Cells arranged in palisades
Schwannoma				Firm to gelatinous			Associated with nerves
Lipoma	Unknown	Lipoma: common in adult to aged dogs; less common in horse and cow; rare in cat, sheep, pig	Legs, thorax, abdomen	Associated with nerve	Lipoma: mature fat cells	Lipomas do not recur	Fatty tumor
Infiltrative lipoma				Lipoma: circumscribed, greasy, soft, white, slightly translucent; float in formalin	Infiltrative lipoma: mature fat cells replacing normal muscle or collagen	Infiltrative lipomas are locally invasive and recur but do not metastasize	Float in formalin
Liposarcoma				Infiltrative lipoma: poorly delineated soft enlargements of muscle or soft tissue	Liposarcoma: round to spindle-cell tumor, cellular, vacuolated cytoplasm	Liposarcomas are locally invasive, may recur, and rarely metastasize	
		Infiltrative lipoma: adult dogs					
		Liposarcoma: rare		Liposarcoma: firmer, nondiscrete, gray to white			
Hemangioma	Unknown	Adult to aged	Hemangioma: dermis or subcutis	Red, brown to black	Interconnecting blood containing channels lined by endothelium	Hemangiomas do not recur	Thrombosis frequent in hemangioma
Hemangiosarcoma (Box 17-16)	Trauma or solar radiation for some types	More common in dogs, less common in cats, horses, cattle, sheep, pigs	Hemangiosarcoma: primary to skin or metastatic from visceral tumor	Circumscribed (hemangioma)	Hemangiosarcoma may resemble fibrosarcoma or have benign appearance (especially if metastatic)	Hemangiosarcoma in white cat ear tip and eyelid recur	Coagulation disorder may be associated with these tumors, especially if tumors are large, malignant, or hemangiosarcomas multifocal
		Foals: congenital hemangiomas	Seen more in white, poorly haired dermis, especially of dogs	Soft		Metastatic potential is high in canine	
				Ooze blood on cut surface			
				Dermal may bleed			

## Pathologic Basis of Veterinary Disease, 4th Edition

Lymphangioma	Some are believed to be congenital in young animals	Uncommon to rare	Lymphatics associated with skin	Poorly defined	Interconnecting channels lined by endothelium, usually without erythrocytes	May be difficult to remove due to dissection along fascia, so tumors tend to recur
Lymphangiosarcoma				Cavernous/spongy		
				Soft		
				May dissect along fascial planes		
Feline ventral abdominal angiosarcoma	Unknown	Adult cats	Ventral abdominal skin		May be difficult to distinguish benign and malignant types	Cat ventral abdominal angiosarcoma is invasive and recurs.
Leiomyoma	Unknown	Very rare	Skin associated with arrector pili muscles, or cutaneous blood vessels	Circumscribed	Interlacing bundles of smooth muscle fibers tend to intersect at right angles	Leiomyoma: benign
Leiomyosarcoma				Solitary		Leiomyosarcoma is locally invasive
				Firm		
Cutaneous nodular fasciitis (overlap with fibrous histiocytoma)	Unknown	Rare	Usually solitary	Solitary, firm	Nuclei have blunt ends	
	Nonneoplastic	Dog and cat	Subcutaneous fascia	Nondiscrete	Mixtures of fibroblasts, giant cells, and inflammatory cells in vascular stroma	Nonneoplastic but can have clinically aggressive behavior
				Subcutaneous	Mitoses present	Similar lesion on cornea/third eyelid, especially in collies, is termed "nodular granulomatous episclerokeratitis"
Benign fibrous histiocytoma (overlap with cutaneous nodular fasciitis)	Unknown	Uncommon: dogs, especially collies	Multiple	Head, face	Mixture of fibroblasts, and histiocytes	May recur
		Rare: cats	Face	Firm		Neoplastic nature questioned
		Younger adult	Dermal	Dermal	Lymphocytes and plasma cells at periphery	probably represent "nodular granulomatous episclerokeratitis"
Malignant fibrous histiocytoma (extraskeletal giant cell tumor)	Unknown	Older ages	Skin of limbs	Firm, solitary	Densely cellular	Locally aggressive
	Pleocellular tumor that probably is either of primitive mesenchymal cell origin, or individual tumors may originate from different cell lines, requiring immunohisto-chemical differentiation	Cats, dogs, horses and neck		Nonencapsulated	spindle cell tumor with two cell types: fibroblastic and histiocytic	Usually slow to metastasize; however, this can depend on cell of origin
		Uncommon to rare		Variable size and shape	Many mitoses	fibroblastic cells
					Multinucleated cells in cats	Giant cells, especially in cats

FeLV, Feline leukemia virus; FeSV, feline sarcoma virus; FIV, feline immunodeficiency virus.

\* Classification and terminology of benign basal cell tumors varies with authors. Differences appear largely related to epidermal versus follicular origin and therefore histologic appearance of the tumors.

The progression of the disease from mere hyperplasia to an invasive carcinoma represents a series of molecular events whereby the population of cells harbors an increasing number of damaged genes belonging to the four categories of genes listed. This series of changes takes place over long periods of time, often years, before a tumor reaches full malignant potential. The process may be halted in the early stages if the agents causing continued genetic damage can be removed (for example, exposure to UV radiation).

Most cutaneous neoplasms are primary, as the skin is an uncommon to rare site for metastasis; however, the skin can be the site of secondary tumor growth. Examples include mammary gland neoplasms that invade into adjacent skin, feline pulmonary bronchogenic carcinomas that metastasize to multiple digits of the feet, and canine visceral hemangiosarcomas that can metastasize to the skin. [Table 17-13](#) gives an abbreviated listing of the salient features of cutaneous neoplasms.

### 17.3 GLOSSARY

#### Acantholysis:

loss of cohesion between keratinocytes due to the breakdown of intercellular bridges.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

**Acanthosis:**

thickening of the spinous cell layer (stratum spinosum).

**Acral:**

distal parts of the extremities.

**Alopecia:**

hair loss.

**Anagen:**

phase of hair cycle in which hair synthesis takes place.

**Anaplasia:**

lack of cellular differentiation and organization, a feature of neoplastic cells.

**Angioedema:**

vascular reaction involving the deep dermis or subcutis and consisting of edema manifested as giant wheals and caused by dilation and increased permeability of capillaries (deeper version of urticaria).

**Apoptosis:**

programmed cell death.

**Atrophy:**

reduction in size of a cell, tissue, organ, or part.

**Ballooning degeneration:**

marked intracellular fluid accumulation in the cells of the epidermis.

**Blister (vesicle or bulla):**

localized collection of fluid usually in or beneath epidermis.

**Bulla:**

large blister (>1.0 cm).

**Catagen:**

transition phase of the hair cycle between growth and resting phases.

**Comedo (plural = comedones):**

plug of follicular stratum corneum and dried sebum in a hair follicle.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

**Cornification:**

production of stratum corneum by terminal epidermal differentiation.

**Crust:**

material formed by drying of exudate or secretion on the skin surface.

**Cytokines:**

small molecular weight protein molecules (generally <30 kD) that are mediators of inflammation and growth.

**Dematiaceous:**

naturally pigmented black or brown mycelium or conidium.

**Dermatitis:**

inflammation of the skin.

**Dermatophytosis:**

infection of the stratum corneum of the epidermis, hair, or claws with fungi of the genera *Microsporum*, *Epidermophyton*, or *Trichophyton*.

**Dermatosis:**

noninflammatory lesion of the skin.

**Dyskeratosis:**

abnormal, premature, or imperfect keratinization.

**Dysplasia:**

abnormal development.

**Effluvium:**

shedding of hair.

**Epidermal collarette:**

peripheral expanding ring of scale.

**Epidermitis:**

inflammation of the epidermis.

**Epidermolysis:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

separation of the epidermis from the dermis.

1259

---

**Erosion:**

1260

loss of all or part of the thickness of the epidermis.

**Eruption:**

rapid development of skin lesion associated with redness.

**Erythema:**

redness of skin due to congestion of capillaries.

**Excoriation:**

superficial loss of epithelium due to physical trauma (scratching).

**Exfoliation:**

shedding of layers or scales.

**Exogen:**

the stage of the hair cycle where old hairs are shed.

**Exudate:**

fluid, cells, or debris from blood vessels deposited in or on other tissues.

**Fissure:**

cleft or groove.

**Folliculitis:**

inflammation of a hair follicle.

**Furuncle:**

circumscribed, painful nodule (accumulation of pus) in the dermis secondary to follicular rupture.

**Genodermatosis:**

a genetically determined disorder of the skin.

**Glabrous:**

smooth skin, hairless skin.

**Hamartoma:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

growth of cells in a localized area that surpasses the growth of cells in the surrounding area, and presumed to be of congenital origin.

### **Hydropic degeneration:**

intracellular fluid accumulation in cells of the basal epidermis.

### **Hyperkeratosis:**

histologic term for thickening of stratum corneum.

### **Hyperplasia:**

increase in the number of normal cells.

### **Hypoplasia:**

incomplete development.

### **Hypotrichosis:**

less hair than normal.

### **Ichthyosis:**

congenital skin disorder in which the skin is thickened by scales (hyperkeratosis) that can crack into plates resembling fish scales.

### **Impetigo:**

bacterial dermatitis characterized by pustules.

### **Indolent:**

slow growing, a term applied to persistent ulcers on the lips of cats, and sometimes incorrectly called "rodent ulcer," a term from the human literature used to refer to ulcerated basal cell carcinoma.

### **Indurated:**

Hardened.

### **Interface:**

inflammation arranged in a layer close to and often obscuring the epidermal-dermal junction (interface), and with vacuolar and sometimes apoptotic basal cells; the inflammation can be mild (cell poor) or extensive (cell rich).

### **Intertrigo:**

dermatitis that develops because of friction between apposing skin surfaces (e.g., adjacent folds).

# Pathologic Basis of Veterinary Disease, 4th Edition

---

**Keratinocytes:**

the epidermal cells that synthesize keratin and comprise more than 90% of epidermal cells.

**Keratosis (plural + keratoses):**

an uncommon to rare circumscribed papular, plaque-like, or linear focus of proliferative keratinocytes covered by thick stratum corneum; keratoses can be caused by sun exposure (actinic keratoses) or can be idiopathic (lichenoid, linear, cannon [metatarsal bone] keratoses).

**Langerhans' cells:**

antigen-presenting cells of the skin.

**Lichenification:**

thickening of skin with accentuation of skin creases.

**Lichenoid:**

confusing term that generally refers to a dense zone of dermal inflammation parallel to the epidermis usually without basal cell injury.

**Lichenoid dermatoses:**

uncommon to rare, often idiopathic, single or grouped papules, plaques, or papillomatous foci covered by scale, and histologically composed of epidermal hyperplasia, lichenoid lymphoplasmacytic dermal inflammation, hyperkeratosis and parakeratosis.

**Macule:**

flat, circumscribed lesion of altered skin color.

**Melanin:**

dark, amorphous pigment consisting of dihydroxy indoxyl acid.

**Melanophages:**

macrophage containing ingested melanin.

**Merkel cell:**

a neuroendocrine cell found in the stratum basale.

**Mucin:**

glycosaminoglycan (GAG), a normal component of the ground substance of the dermis, consists of protein bound to hyaluronic acid.

**Mycelium:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

a mass of hyphae.

### **Mycetoma:**

a slowly progressive infection of the cutaneous and subcutaneous tissue, fascia, and sometimes underlying bone caused by traumatic implantation of actinomycetes (actinomycotic mycetoma) or fungi (eumycotic mycetoma).

### **Myxedema:**

nonpitting edema of the skin because of abnormal deposits of mucin in the dermis.

### **Nevus:**

circumscribed malformation of the skin assumed to be of congenital or inherited origin, and consisting of any component of the skin. The term “hamartoma” is preferred to nevus to avoid confusion with the pigmented nevus (mole) that arises in the skin of human beings.

### **Nodule:**

a circumscribed, solid elevation of skin (>1 cm).

### **Onychodystrophy:**

abnormal formation of the claw.

### **Onychomadesis:**

sloughing of claws.

1260

---

### **Panniculitis:**

1261

inflammation of subcutaneous adipose tissue.

### **Papule:**

circumscribed, solid elevation of skin (<1 cm).

### **Parakeratosis:**

retention of pyknotic nuclei in epidermal cells of the stratum corneum.

### **Paronychia:**

inflammation of skin around the claws.

### **Pemphigus:**

cutaneous disease associated with blistering.

### **Phaeohyphomycosis:**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

mycotic disease caused by pigmented fungi (dematiaceous fungi) of a variety of genera and species that do not form sclerotic bodies or granules.

**Pigmentary incontinence:**

melanin pigment within dermal macrophages or free in the dermis developing via injury to pigment containing basal layer cells.

**Plaque:**

a flat-topped, solid elevation in the skin that occupies a relatively large surface area in comparison with its height.

**Pruritus:**

itching.

**Pustule:**

small, circumscribed accumulation of pus within the epidermis or within a hair follicle.

**Pyoderma:**

pyogenic (pus-producing) bacterial infection of the skin.

**Rodent ulcer:**

a term used in human medicine to define an ulcerative basal cell carcinoma; sometimes used inappropriately in veterinary medicine to refer to an indolent ulcer affecting the lip of cats.

**Scale:**

a thin, platelike accumulation of stratum corneum on surface of skin.

**Seborrhea:**

nonspecific term for clinical signs of scaling, crusting, and greasiness. Primary seborrhea is a more specific term applied to inherited cornification disorders.

**Sebum:**

secretion of sebaceous glands.

**Spongiosis:**

intercellular edema which, by widening of the intercellular space and stretching of the “intercellular bridges,” creates a spongelike appearance to the epidermis.

**Telogen:**

resting phase of the hair cycle.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### **Ulcer:**

loss of epidermis and at least the superficial portion of dermis.

### **Urticaria:**

usually transient vascular reaction in the upper dermis consisting of edema manifested clinically as wheals (hives); a more superficial version of angioedema.

### **Vesicle:**

small blister within the epidermis or at or below the dermal-epidermal interface (<1.0 cm) (Fig. 17-19).

### **Vibrissa (plural = vibrissae):**

(sinus hair, tactile hair) long, coarse hair located about the nose.

### **Vitiligo:**

acquired disorder characterized by circumscribed areas of depigmentation in the skin.

### **Wheal:**

smooth, circumscribed, slightly elevated area on skin caused by dermal edema.

### **Yeast:**

unicellular budding fungus.

## 18 Chapter 18 Female Reproductive System\*

ROBERT A. FOSTER

The reproductive system is arguably the most important in terms of survival of a species. In production animals, reproduction is essential for the continued supply of product, be it meat, fiber, milk, or any of the many other by-products. Diseases of the reproductive system have not changed much in the last few decades, but our understanding of many of the processes has progressed dramatically and many of the accepted “dogmas” have now been challenged and/or modified. In addition, the traditional approach to diseases of the reproductive system has focused on information about specific conditions for which some information is known, rather than taking into consideration the overall significance in a clinical setting. In this chapter, each component or region will be examined in turn; however, the relative importance of specific diseases or processes will be emphasized. The traditional approach also concentrated on bovine and, to a lesser extent, equine reproductive diseases. In this chapter, diseases of all species including companion animals will be undertaken.

### 18.1 INTRODUCTION

#### 18.1.1 ORGANIZATION

##### 18.1.1.1 FEMALE REPRODUCTIVE SYSTEM

The female reproductive systems of domesticated animals, although diverse in anatomy, share many similarities in structure and function. Whereas the female reproductive tract was thought to be the embryonic default when the male reproductive tract did not form, it is now considered to involve unique actions of various genes and subsequent processes.

Genes initiate the pathways of ovarian differentiation and development. *DAX1* is one such gene that both promotes ovarian development and inhibits testicular development. In development of the ovary, the germ cells undergo meiosis and the supporting cells surround the oocytes to become the cells of the follicles. Steroid-producing cells become the thecal cells. The differentiation of a female phenotype occurs with the development of the paramesonephric (Müllerian) ducts to form the uterine tube, uterus, and upper part of the vagina, and for the genital tubercle to develop into the distal vagina and vulva.

The structural arrangement of the ovary is relatively uniform except in the mare. The ovary itself has an outer layer of epithelium, which is of mesothelial origin. The cortex of the ovary contains follicles, stromal connective tissue, and blood vessels. The medulla has many large blood vessels, lymphatics, nerves, and loosely arranged connective tissue. Remnants of the mesonephric tubules, called the rete ovarii, are present in this region.

The follicles are where the ova develop, and they are named according to their stage of development: primordial, primary, secondary, and tertiary types. Each developing follicle has multiple layers of granulosa cells and more peripheral thecal cells. Ovulation occurs when the follicle ruptures, releasing the ovum and allowing the space to fill with blood and then with luteal cells to form the corpus hemorrhagicum and corpus luteum, respectively. Follicles that do not ovulate become atretic. In addition to these various ovarian structures, cats have interstitial glands that are cells of an endocrine type. The canine ovary has small ingrowths of the ovarian surface that are called subsurface epithelial structures.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Oogenesis is usually completed by birth. In most species, ovulation occurs through the outer surface of the ovary from whence the ovum is collected by the infundibulum.

The ovary of the mare differs from the other species in several ways. Equine fetal gonads undergo hypertrophy wherein interstitial glands expand and produce a gonad that is extremely large. Stimulation by pregnant mare gonadotropins is believed to induce the large size. These atrophy before birth. The ovary of the mare has a kidney shape with a depression that is called the ovulation fossa. It is from this small depression that the ovum is released. The cortex of the ovary extends into the center of the gonad, and the “medulla” is at the periphery. The follicles in the mare can attain a large size—up to 7 cm. Mares can therefore form a large corpus hemorrhagicum. On occasion, this and the corpus luteum can extend out through the ovulation fossa.

1263

1264

The uterine tube has four regions—the infundibulum, ampulla, isthmus, and uterotubal junction. It is supported by a mesosalpinx. The mesosalpinx of the dog completely surrounds the ovary and has a large amount of fat; a small hole connects the bursa to the abdominal cavity. The infundibulum surrounds the ovary of each species, except in the horse where it only covers the ovulation fossa. The uterine tube is where fertilization occurs, and the conceptus then moves into the uterus.

All species have a bicornuate uterus with uterine horns and a uterine body. In ruminants, each uterine horn contains four rows of protuberances that are the caruncles. These can be pigmented in sheep. The placenta of ruminants is cotyledonary. The uterus of the mare has longitudinal folds. Endometrial cups are formed between 37 and 150 days of gestation and are the site of production of pregnant mare serum gonadotropins (Fig. 18-1). These typically form around the pregnant horn at the bifurcation. Their disappearance is an immune-mediated event. The placenta of the horse is diffuse and microcotyledonary. Dogs and cats have a zonary placenta with a marginal hematoma. The placenta of the pig is diffuse with small villi.

**Fig. 18-1 Endometrial cups, uterus, mare.** Endometrial cups are plaquelike structures in the endometrium that form when trophoblasts invade the endometrium early in pregnancy. They are present between 37 and 150 days of pregnancy. The chorionic surface opposite each cup is called the chorioallantoic pouch and is avillous. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The cervix is the structure that separates the external genitalia from the uterus and is an effective barrier from the external environment. Cervical mucus is viscous except during estrus when it becomes more plentiful and thinner. The cervix in the mare, dog, and cat does not have transverse folds as it does in the ruminants and sows. The cervix of the dog and cat tends to open dorsally.

\* Previous chapters on this subject were authored by Dr. H. Acland of the Pennsylvania Veterinary Laboratory, Harrisburg, Pa.

### 18.1.1.2 MAMMARY GLAND

#### 18.1.1.2.1 Mammary Development, Lactation, and Involution

Embryologically the mammary glands arise from the mammary ridge that is formed by ventrolateral ectoderm. Mammary buds push into mesenchyme with their number equaling the number of glands. Sprouts form from each bud, and the number determines the number of openings and therefore papillary ducts—1 in cattle, sheep, and goats; 2 in horses and pigs; 3 to 7 in cats, and 8 to 14 in dogs. Glands develop in male embryos, but in domesticated species they only regress fully in the stallion.

As puberty approaches, there is branching of ducts mediated by prolactin, growth hormone and insulin-like growth factors, and many other factors. There is an intimate interaction between the mesenchyme and epithelium, as the ducts branch and alveoli eventually develop. With the onset of lactation, mammary development is at its zenith. Milk flows from the alveoli through the lactiferous ducts to a lactiferous sinus (in large animals) and, with suckling, through the papillary duct or ducts.

There is variation between the species in the amount of regression that occurs when milking ceases. As expected, there is a reduction in the area of secretory epithelium, and a relative increase in the amount of stroma of the gland. When secretion ceases completely, any mammary fluid is resorbed. Bovine mammary glands do not regress as much as in other species, and as such have completed involution in about 2 weeks. Ewes take about 4 weeks to involute. Leukocytes infiltrate the involuting gland; macrophages are most numerous.

### 18.1.2 FUNCTIONS

#### 18.1.2.1 FEMALE REPRODUCTIVE SYSTEM

The overall function of the female reproductive tract is to provide a location for the conception, development, and eventual release of viable offspring. One offspring is sufficient for dairy cows, but the largest number possible is required for production animals. Each anatomic site has its own particular function.

The function of the ovary is to develop and release an ovum or ova and to produce hormones, such as estrogen and progesterone, that influence animal behavior and affect other organs and tissue to maintain pregnancy.

1264

The uterine tube acts as a transport system and storage site for spermatozoa. It also collects and transports the ovum or ova and provides a location for fertilization. The conceptus that is formed is nourished and eventually transported to the uterus for subsequent development.

1265

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The uterus provides a sterile and inert environment for the development of the conceptus. Exchange of nutrients and trophic factors, immunologic components such as immunoglobulin molecules, and waste products is a major function. This is achieved via placental attachment sites that increase the surface area of the interface between maternal and fetal tissue. At the appropriate time, the muscles of the uterus contribute to the release and birth of the developing individual.

The cervix has a gatekeeper function of holding the products of conception within the uterus until the appointed time. It also provides a seal that prevents entry of organisms and substances from the cranial vagina. Its dilation is an important part of parturition.

The vagina and vulva provide a passageway that allows an internal site for the deposition of semen. This protects the spermatozoa from desiccation and excessive contamination with organisms and materials that would excessively irritate or infect the uterus and uterine tube. The vagina also has a function in reducing contamination of the cervix, especially during pregnancy. It is also a portal for the fetus at parturition.

### 18.1.2.2 MAMMARY GLAND

The mammary glands have the basic function of providing immunity and nutrients to neonates. Milk is the source of many defenses, including antimicrobial, antiinflammatory, and immune-modulating molecules and substances. In the immediate neonatal period, passive transfer of immunoglobulin via colostrum is an important means of providing immediate immunity to offspring of all domestic species. Most domestic species rely on colostrum entirely in the first 24 hours as the sole source of serum immunoglobulin. Dogs and cats are exceptions, as there is some transplacental transfer. Components of the cellular immune system, such as lymphocytes and cytokines, are also transferred in milk. After the immediate postnatal period, substances in ingested milk (including immunoglobulin) provide some local protection against intestinal and respiratory pathogens.

The mammary gland of the modern dairy animal is expected to provide much more milk than is necessary for these functions, and the high-producing dairy cow is a special creature, developed to provide a product of good quality with a long shelf life and with modifications to the components of milk to suit consumers. This includes high production with a low somatic cell count.

### 18.1.3 CELL TYPES

#### 18.1.3.1 FEMALE REPRODUCTIVE SYSTEM

The cells of the ovary are unique, but those of the rest of the tract are of a type seen in other locations. In general terms, much of the reproductive system has a barrier between the external environment and the internal environment that is based on epithelium and on an active mucosal immune system. Superimposed on this arrangement are the modifications that occur with the estrus cycle and with pregnancy.

The cell types of the ovary include the epithelium (surface epithelium, subsurface epithelial structures of the bitch, and the rete ovarii), the stroma, germ cells, and follicular cells. Lymphoid cells are usually absent. Control of ovarian function is from the hypothalamus and pituitary through release of gonadotropin-releasing hormone (GnRH) as well as follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (see [Fig. 12-4](#)).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The uterus is a unique environment that is separated from the external environment by the cervix. Because it is designed to protect and nourish the fetus, there are some unique features of the endometrium. The endometrium has an epithelial lining of columnar and sometimes ciliated cells. There is also a stromal component of the endometrium. Inflammatory and immune cells are present, particularly during estrus, when the uterus is open to the external environment and to spermatozoa or semen (horses and pigs have intrauterine insemination). Mild inflammation is a “normal” part of the estrus cycle.

The “external” component of the female reproductive tract, being the vulva, vagina, and part of the cervix, is lined by a stratified squamous epithelium that varies with the stage of cycle. This is best illustrated in the bitch and queen, in which vaginal cytology is used as a practical guide to determine the stage of cycle. During anestrus, the epithelium is predominantly of a basal type, having a large nucleus and a small amount of cytoplasm. With the progressive approach of estrus (i.e., during proestrus), the epithelium becomes more mature so that at estrus the majority of cells are superficial epithelial cells with either pyknotic nuclei or no nuclei. Lymphoid follicles beneath the epithelium are a normal part of the distal vagina.

Pregnancy brings about a world of change to the reproductive system. The maintenance of pregnancy and the exchange of nutrients between mother and fetus and of other products from fetus to mother depend on the interactions of the trophoblasts with the endometrium. During pregnancy, the trophoblasts are directly opposed and in contact with the endometrial epithelium. In cattle, the maintenance of pregnancy depends on the inhibition of prostaglandin  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ) production in the endometrium so luteolysis does not occur.

1265

1266

The trophoblast must avoid rejection by the mother and maintain a barrier yet provide a system for the exchange of nutrients and waste products. There is much to be learned about the enigma that is pregnancy.

Some of the cells that we would ordinarily consider “inflammatory” cells have specific and individual functions separate from their usual roles. Thus uterine macrophages, natural killer cells, and, even in some cases, neutrophils have separate and distinct functions. For example, macrophages are important in maintaining the size and shape of bovine caruncles,  $CD2^+$  T lymphocytes and natural killer–like cells are important in early pregnancy in pigs, and neutrophils are involved in cervical relaxation at parturition in sheep. Thus the usual function of inflammatory cells can be modified or used by the reproductive tract for specific but otherwise unexpected purposes that result in the maintenance of pregnancy.

18.1.3.2

### MAMMARY GLAND

The mammary gland is sequestered from the outside world by the gatekeeper functions of the sphincter of the mammary papilla (teat) and the papillary duct and, at least in the ruminant, its lining of keratinized squamous epithelium. The lactiferous sinus and ducts are lined by columnar epithelial cells, and the alveoli have the secretory epithelium. Secretion of milk components occurs in the alveoli. Mammary epithelial cells, specifically the alveolar cells, have receptors for immunoglobulin G (IgG); they are present for about 1 week before parturition, but the receptors disappear during lactation. Epithelial cells also allow for the transfer of IgA, which is produced locally in subepithelial plasma cells, into the alveolar lumens.

Lymphoid cells in the normal gland are derived from blood, and there is also homing of lymphocytes from the intestine (the enteromammary link) as part of the common mucosal immune system. Lymphocytes of the cellular immune system are present also, but in low numbers.

## 18.1.4 RESPONSES TO INJURY

### 18.1.4.1 FEMALE REPRODUCTIVE SYSTEM

Little is known about the response of the ovary to infection or insults. Observations of neutrophilic and, in viral infections, lymphocytic inflammation indicates that the ovary is capable of inflammatory and immune responses as one would expect with other parts of the body. Hyperplasia of the surface epithelium is a common response, just as it is with mesothelium elsewhere.

The uterine tube is such a narrow structure that its function is altered readily with edema, inflammation, and scarring. Exocytosis of neutrophils from blood vessels via the interstitium can be rapid. In sufficient numbers, pus is formed. Local immune responses can develop and result in the accumulation of lymphocytes, plasma cells, and, in some instances, lymphoid follicles. Granulation tissue formation in severe inflammatory conditions leads to scarring and subsequent obstruction of the tube is followed by an accumulation of fluid (hydrosalpinx) or pus (pyosalpinx).

Much has been studied about the responses of the uterus to infection. Inflammation varies from mild, in the case of postmating endometritis, to severe in bacterial metritis and pyometra. In mild acute inflammation of the endometrium (endometritis) of species—apart from the dog and cat—neutrophils and macrophages migrate through the epithelium into the lumen, and the stratum compactum is edematous. This becomes more florid with an increased severity. Neutrophils and necrotic debris accumulate in the uterus until pyometra forms. Lymphocytes and plasma cells accumulate in the stroma of the endometrium. With chronicity and in severe situations, the epithelium becomes squamous and so there is squamous metaplasia. Necrosis and erosion of the epithelium will induce the formation of granulation tissue, and varying degrees of fibrosis are commonplace in severe infectious or inflammatory disease.

The canine endometrium in particular, and also the feline endometrium, responds with cystic endometrial hyperplasia. Any injury or insult, be it inert foreign material or pathogenic infectious agents, will stimulate this response. This occurs in diestrus, and the luminal epithelium becomes papillated and can resemble a placental site.

Because of the stratified squamous epithelium of the vulva and vagina, inflammation and infection of the external part of the reproductive tract results in hyperplasia and keratinization. Exocytosis of inflammatory cells does occur, predominantly with neutrophils. These inflammatory cells do so with some difficulty because of the intercellular junctions. The inflammatory response is typically lymphocytic and plasmacytic, and these cells form a thick band of cells beneath the epithelium. Lymphoid follicles often form and give the affected region of the vagina a granular macroscopic appearance.

Reactions of the placenta are stereotyped and rely heavily on the maternal response and, to a lesser extent, the fetal immune systems. There is some species variability that can be related to the types of placenta and the usual route of infection. The response of the fetus and placenta tends to be relatively rudimentary. Trophoblasts are phagocytic, and they will take up debris, blood, and infectious agents. Reactions of fluid exudation and of connective tissue with granulation and fibrosis occur as elsewhere. The reactions of fetal macrophages and neutrophils are less obvious than is seen where maternal leukocytes are readily accessible. Placentitis occurs when there is sufficient time for a response: Fetal loss can be rapid with fetal distress, and there can be insufficient time to mount an effective response. Chronic lesions are much more obvious and are seen in ruminants especially. The cotyledonary placenta means that attachment of the placenta to the

1266

1267

## Pathologic Basis of Veterinary Disease, 4th Edition

---

endometrium is restricted to a relatively small area in relation to the total placental area. The intercotyledonary area is a potential space that can accumulate a large volume of exudate. Chronic inflammation in ruminants is typified by fibrosis and exudates of suppurative material. Lymphoid follicles and plasma cells are a lesser component of the reaction, but lymphocytes do accumulate beneath the layer of trophoblasts and around blood vessels. The neutrophils are probably mainly of maternal origin. In the equine placenta, placentitis involves a small area, usually around the cervical star. There is no potential space because of the diffuse microcotyledonary type of placenta, so exudates and suppuration are much less prominent, and chronic placentitis is rare. The inflammatory reaction in the pig, dog, and cat is mild and is rarely seen because chronic placentitis is very rare.

18.1.4.2

### MAMMARY GLAND

The mammary gland is usually sterile, but it can respond rapidly to infection or other irritants. The responses are relatively stereotyped, however. The columnar epithelial cells can become hyperplastic, but the cells are not able to withstand injury to the same extent as stratified epithelium, so squamous metaplasia is a frequent occurrence when irritants, such as infection or intramammary preparations, are introduced. Necrosis of the epithelium is common in infectious disease, and granulation and scarring of the lining of the ducts and sinus are frequent.

Although the immune system of the normal mammary gland is quiescent, injury quickly results in recruitment of the various elements. Neutrophils and macrophages are rapidly recruited. Humoral and cellular immunity is typically seen in infectious conditions. The accumulation of large numbers of plasma cells, recruited to the area because of the development of a local immune system, is an invariable component of the immune response in infection. Edema and subsequent fibrosis are part of the reaction to injury. The flow of milk is often halted by injury and exudates, so the normal involutionary processes that result in resorption of secretion (macrophage and epithelial uptake) also operate.

18.1.5

### PORTALS OF ENTRY

18.1.5.1

#### FEMALE REPRODUCTIVE SYSTEM

It is critical that organisms are excluded from the uterus; otherwise fertility or pregnancy can be jeopardized. Portals of entry are listed in [Box 18-1](#). Organisms that cause inflammation of the uterus can enter through the vulva (ascending infection) or can arrive via the blood (hematogenous infection). Reinfection of the external genitalia from nerves is a unique feature of infection with some herpesviruses.

18.1.5.1.1

#### Box 18-1 Portals of Entry into the Female Reproductive System, Especially the Uterus

Ascending infection through cervix

- At insemination
- Excessive vaginal contamination
- Postpartum and with retained fetal membranes

## Pathologic Basis of Veterinary Disease, 4th Edition

### Hematogenous

- Localization in maternofetal interface

Descending from ovary via uterine tube

Transneural with recrudescence of herpesviruse infection

Ascending infections are initiated at estrus, breeding, and parturition. At estrus, the cervix is open to admit spermatozoa. Contamination of the cranial vagina is very important in determining whether infection of the uterus occurs or not. Conformational and structural changes in the vulva and vagina are also important determinants of infection. These will be discussed in more detail later. A subcategory of ascending infection is infection of semen by infectious agents. There are many agents, including bacteria, viruses, protozoa, and *Ureaplasma* and *Mycoplasma*, some of them with a recognized venereal transmission, which can be acquired in this fashion. These will be discussed further in examining diseases of the uterus. Ascending infection is the major portal by which the equine placenta becomes infected with bacteria or fungi. The cervix in the mare is “loose,” attains a much larger diameter, and can be readily opened with digital pressure. It is virtually impossible to penetrate the cervix of other species with a probe without creating severe trauma. Infection of the uterus and or placenta by the ascending route with a pure culture of *Streptococcus zooepidemicus* is common in the mare, but most ascending infections in other species includes a mixture of bacteria. This is particularly the case with postpartum infection.

Hematogenous infections are less common and are usually involved in specific infections, such as in brucellosis, salmonellosis, pestiviral and herpesviral infections, and they usually occur during pregnancy. Many of the fungal infections of the placenta occur via the hematogenous route.

There are some instances in which infections appear to descend from the ovary through the uterine tube. Some viral, chlamydial, and *Ureaplasma* infections can be descending.

1267

Direct penetration

- Penetrating injury

Transaxonal infection of the distal reproductive tract occurs with some herpesviruses, where stressful events such as parturition cause a recrudescence. Neonates can be exposed and infected via this route, but clinical disease in the mother is unusual.

### 18.1.5.2 MAMMARY GLAND

Portals of entry are listed in [Box 18-2](#). Most infectious agents and foreign material (intramammary preparations) enter the gland in an ascending fashion via the papillary duct. Small (bacteria) and large (leaches) pathogens can enter the gland via this route. There are some instances where organisms home to the mammary gland from systemic infection, but their number is small. Viruses such as the retroviruses of caprine arthritis and encephalitis, ovine maedi-visna, and *Mycoplasma* spp. are good examples. Penetrating injury is rare.

### 18.1.6 DEFENSE MECHANISMS

#### 18.1.6.1 FEMALE REPRODUCTIVE SYSTEM

Whereas the adaptive immune system has been a focus of attention in defense of the reproductive system, innate, nonimmune, or physical factors are much more important. In many instances, failure of the physical factors, and infection of the tract, is too late for the fetus and infertility and failure of pregnancy occurs. Defense mechanisms are listed in [Box 18-3](#).

#### 18.1.6.1.1 Innate Immunity

The reproductive tract requires much of its defense system, as it must provide a sterile environment for the fetus but allow entry of antigenic and infectious materials (semen). It does this by providing specialized epithelium in the “contaminated” environment of the vulva and vagina, and then has a specialized structure, the cervix, to exclude most agents from the upper “sterile” regions. Vaginal epithelium has intercellular tight junctions that inhibit the transepithelial migration of agents and molecules and is likely to have molecules that detect pathogen-associated molecular patterns. These molecules, presumably including defensins, exclude or direct actions against many pathogens.

#### 18.1.6.1.1.1 Box 18-3 Defenses of the Female Reproductive System

Innate defenses

- Vaginal epithelium
- Cervical barrier
- Conformation

## Pathologic Basis of Veterinary Disease, 4th Edition

- Myometrial tone and contraction
- Drainage of secretions
- Neutrophils
- Macrophages
- Complement
- Cytokines

### Adaptive defenses

- Humoral immunity including common mucosal immune system
- Cellular immunity

The anatomy and integrity of the cervix is very important in the exclusion of infectious agents from the uterus. Contamination of the cranial vagina is an additional factor, and so conformation of the external genitalia is the physical factor that has received the most attention in relation to uterine infections. In older multiparous mares, the vulva is frequently higher than the floor of the pelvic canal and tends to become horizontal; air and contaminants, including feces, will be sucked in or allowed entry into the vagina or even into the uterus. Urine can pool in the vagina of mares with defective function of the vestibule and vulva muscles. When contamination and pooling of urine occur, the vestibule and vagina become inflamed, and the cervix and uterus become inflamed at the onset either from direct contact with environmental organisms or from local spread of the inflammation.

Muscular contractions of the uterus and gravitational drainage of secretions (mucus, lochia) from the uterus and vagina is a physical factor that can flush out infectious organisms. Congenital malformations and anomalies, such as persistent hymen, can reduce outflow and increase pooling in the vagina and uterus. The altered environment of the vagina in spayed, obese bitches can predispose the vagina and vulva to infection.

Following infection or irritation from semen, changes include hyperemia and edema of the uterine wall and lumen. These have the theoretical effect of diluting infectious or irritant substances. Recruitment of neutrophils from the blood occurs in response to chemotactic substances released by bacteria, complement, and inflammatory mediators from endometrium and leukocytes. Attracted neutrophils infiltrate the endometrium and enter the uterine lumen and contribute additional amounts of inflammatory mediators, providing additional chemotactic stimuli. Complement activation, directly by bacteria via the alternate pathway or by specific antibody via the classical pathway, can eliminate bacteria either by lysis following attack on their membranes or by phagocytosis enhanced by opsonization.

1268

1269

### 18.1.6.1.2

#### Adaptive Immunity

The reproductive tract is a unique environment because it must respond adequately to challenge from pathogens, yet tolerate the allogeneic spermatozoa and fetus. Adaptive immune responses, be they

## Pathologic Basis of Veterinary Disease, 4th Edition

---

humoral or cellular, have to be carefully controlled. Control is achieved by differing cytokine expression of epithelial cells and their effects on regulatory T lymphocytes that make “decisions” as to the type and extent of the response. There is likely to be variation in the response, depending on the location. The response in the “sterile” compartments of the uterus and uterine tube will be different than that of the “nonsterile” vagina and ectocervix.

Although the upper reproductive tract is part of the common mucosal immune system, it differs from intestinal and bronchial tissues because it does not have mucosal-associated lymphoid tissue analogous to Peyer's patches. This is no doubt because of the lack of continuous antigenic stimulation. Lymphoid follicles, however, are present in the vulva and distal vagina. The uterus also has the added potential influence of hormones to modify responses.

T lymphocytes are critical in determining whether the appropriate response is predominantly humoral or cell mediated. CD8<sup>+</sup> T lymphocytes are the most common lymphocytes of the luminal endometrial epithelium and stroma (stratum compactum especially), although there is variation depending on the location in the uterus. For example, CD4<sup>+</sup> lymphocytes are more common in the horns of the uterus of mares, whereas CD8<sup>+</sup> lymphocytes are more numerous in the body.

Little is known of the T lymphocyte and cell-mediated immune system of the reproductive tract; much more is known about its humoral immune system. It is generally believed that locally produced antibodies are more important in those diseases that are acquired by ascending infection, for example, *Tritrichomonas foetus* in cattle, whereas systemic immunity is more important in systemically or hematogenously acquired infections, such as *Brucella* sp. infection. The immunoglobulin isotype (IgA or IgG) and subisotype (IgG<sub>1</sub> or IgG<sub>2</sub>) that is found in an individual infection is unique to that infection. The generalization that IgA is the main mucosal antibody is not always the case. The response to specific infectious agents is not uniform, and there are differing responses between species. Protection against *Tritrichomonas foetus* in cattle, for example, is mostly by IgG<sub>1</sub>. Local transfer of immunoglobulin occurs at all levels of the tract.

Leakage of serum into the uterine lumen from an inflamed endometrium also contributes to the antibody content of the uterine fluid. Opsonization of bacteria by antibodies, especially IgG, promotes more efficient phagocytosis by neutrophils and macrophages; thus they enhance the innate cellular response by phagocytes.

The influence of the estrus cycle on antibodies in the uterus is controversial, but data suggest that concentrations of luminal immunoglobulins and immunoglobulin-containing cells in the endometrium are not influenced by the stage of the estrus cycle.

Locally produced IgA interferes with attachment of bacteria to mucosal surfaces and can activate complement via the alternate pathway. It is not directly bactericidal and neither acts as an opsonin nor as a macrophage activator. Variations occur among species on the position in the tract where the concentration of IgA is greatest, but the sites correspond to the site of semen deposition (uterus in mares, vagina in cows).

### 18.1.6.1.3

#### Hormonal Influences on Innate and Adaptive Immunity

Infections of the uterus are more easily overcome at estrus than at other stages of the cycle. This increased response at estrus is probably due, at least in part, to better drainage through an open cervix.

## Pathologic Basis of Veterinary Disease, 4th Edition

Both estrogen and progesterone affect neutrophil and lymphocyte function, but there is variation in results obtained when the effects of hormones have been studied. In some species, such as the mouse, estrogen induces an influx of neutrophils and macrophages (at estrus). Estrogen can also be involved in the up-regulation of subsets of T lymphocytes. There is variation in the numbers of lymphocytes in the reproductive tract during the estrus cycle. Even so, there is evidence that CD4<sup>+</sup> lymphocytes increase in number with increases in estrogen. Progesterone, which dominates during the luteal phase and pregnancy, antagonizes the “proinflammatory” activity of estrogen. Studies in cattle and sheep indicate an up-regulation of T- and B-lymphocyte responses during the follicular phase of the estrus cycle, when estrogen dominates. Major histocompatibility antigen II expression is enhanced at estrus in direct relationship with rising estrogen concentration. The influence of the estrus cycle on antibodies in the uterus is controversial, but data suggest that concentrations of luminal immunoglobulins and immunoglobulin-containing cells in the endometrium are not influenced by the stage of the estrus cycle. Generally the uterus is more susceptible to infection during the progestational or luteal phase of the estrus cycle and during pregnancy. The nonpregnant uterus is highly resistant to infection. The mechanisms involved in the effect of sex hormones on neutrophils is unknown, and receptors for sex hormones have not been demonstrated in them.

1269

1270

Prostaglandins are normally produced by the endometrium. In most species (excluding the dog, cat, and primates), prostaglandins are responsible for lysis of the corpus luteum. In acute inflammation, prostaglandin production by the endometrium is increased, and lysis of the corpus luteum occurs. When chronic inflammation progresses to the stage of epithelial and mucosal surface loss, production of prostaglandins is decreased, and the corpus luteum persists, with the result that the more susceptible environment of a progestational uterine environment is maintained.

18.1.6.2

### MAMMARY GLAND

As with the body in general, the mammary gland has a full range of mechanisms to prevent and control infectious disease. It relies heavily on isolation. The structure and function of the papillary duct of the teat, and the keratin that accumulates there to form a plug, prevents many potential pathogens from entering the gland. Secretions of the gland contain antimicrobial, antiinflammatory, and immune-modulating substances. Within the gland, there also are humoral and cellular defenses. Defense mechanisms are listed in [Box 18-4](#).

18.1.6.2.1

#### Innate Immunity

Physical factors are very important in the resistance to infection. The teat orifice, with its sphincter, and the papillary duct offer mechanical resistance to the entry of organisms. The keratin and waxy nature of the inner aspect of the papillary duct can be protective by having bactericidal fatty acids, by adsorbing bacteria and desquamating when coated with bacteria, and by desiccating. Delays in the formation of the keratin plug at drying off or cracks in the teat ends increase the risk of intramammary infection. Regular milking of the lactating mammary gland probably is a natural defense mechanism because of the flushing of organisms and products of inflammation from the gland.

18.1.6.2.1.1

#### Box 18-4 Innate or Nonspecific Defenses of the Mammary Gland

Physical factors

- Sphincter and keratin of teat orifice

## Pathologic Basis of Veterinary Disease, 4th Edition

- Flushing action of milk

### Soluble factors

- Lactoferrin
- Lysozyme
- Complement
- Cytokines

### Cellular factors

- Macrophages
- Neutrophils
- Natural killer cells

Soluble factors are numerous and contribute to resistance to infection. Lactoferrin, the major iron-binding protein of saliva and milk, is a nonspecific natural protective factor in milk. Mammary gland epithelial cells produce the bulk of lactoferrin in milk. Lactoferrin concentration is increased in acute mastitis and in the involuting gland. The binding of iron withholds this essential nutrient from pathogenic bacteria and thus has a bacteriostatic effect. The lactoperoxidase-thiocyanate- $\text{H}_2\text{O}_2$  system temporarily inhibits some streptococci and coliforms and *Staphylococcus aureus*. Lactoperoxidase is synthesized by mammary gland epithelium, thiocyanate is derived from certain green feeds, and  $\text{H}_2\text{O}_2$  is produced by enzymic constituents of milk by streptococci or from an exogenous source. Hypothiocyanite produced by the lactoperoxidase system damages the inner bacterial membrane, killing the bacteria. Lysozyme, synthesized locally or from blood, destroys bacteria by lysis of cell wall peptidoglycan. Complement activated in mastitis by the alternate pathway in response to the presence of bacterial endotoxin can be important in bactericidal activity, opsonization, and promoting inflammation. Normal milk is antiinflammatory. Cytokines have a broad range of immunomodulation. Molecules of this general group include the interleukins (IL-2 especially), colony-stimulating factors, interferons, and tumor necrosis factor.

Cells that are not part of the adaptive or acquired immune system include the macrophages, neutrophils, and natural killer cells. Macrophages are usually the most numerous leukocyte in mammary secretions. They phagocytose bacteria and act as antigen-presenting cells. Macrophages can be found free in the alveoli and the interstitium, as well as in the lamina propria of the lactiferous sinus and interlobular and intralobular lactiferous ducts. In a lactating cow, apparently at least 500,000 phagocytes per milliliter of milk are necessary for defense of the mammary gland against invading bacteria. In an uninfected bovine mammary gland, 50,000 to 200,000 neutrophils and macrophages are found per milliliter of milk, with the macrophages predominating. Lymphocytes represent about 10% of the leukocytes in lactation. Neutrophils are present only in low numbers unless there is bacterial infection or injury, when their influx can be dramatic. Neutrophils play an extremely important role in antibacterial action by phagocytosis and the release of antibacterial substances. Their function is inhibited in the periparturient

1270

1271

## Pathologic Basis of Veterinary Disease, 4th Edition

---

period. Recruitment of neutrophils from the blood to an infection site is one of the first steps in an inflammatory response. Recruitment can be rapid, so that neutrophils are the dominant cells as early as 2 hours after infection. Cell counts in milk can average 700,000 per milliliter in subclinically infected quarters, and millions of neutrophils per milliliter are common in clinical infections.

In experimental staphylococcal mastitis, the numbers of inflammatory cells (mostly neutrophils) in milk cycle up and down every several days, with a corresponding inverse cycling of the number of viable bacteria. When cell counts are at a peak, bactericidal activity per cell is most efficient, by as much as 10,000-fold, and phagocytosis is optimal. The frequency and periodicity of the cycle, as well as the amplitude of the cell and bacterial counts, are independent for each infected quarter. The likely source of reinfection of the mammary gland are neutrophils that are inefficient at killing phagocytosed bacteria at the time of low cell count. As these cells undergo necrosis and lysis, their previously protected intracellular viable bacteria are released to multiply, and the inverse cycling of neutrophils and bacterial numbers continues.

Although neutrophils recruited from the blood are important in fighting infection in the mammary gland, they do not kill bacteria as well in milk as they do in blood. Milk seems to be a poor medium for the functioning of neutrophils. Some possible reasons include the absence of glucose in milk for the glycolytic metabolism of neutrophils, decreased amounts of glycogen in milk neutrophils, deficiency of opsonins and complement in milk, coating of the surface of neutrophils with casein, loss of neutrophil pseudopodia caused by phagocytosis of fat, and a decrease of hydrolytic enzymes within neutrophils after phagocytosis of casein and fat.

In the first week after parturition, when neutrophils are likely most needed to deal with mammary gland infections, bovine blood neutrophils already are defective before they pass into the mammary gland. They have significantly impaired chemokinesis and decreased superoxide anion production, antibody-dependent cell-mediated cytotoxicity, and phagocytosis of bacteria. The causes are probably some combination of the effects of stress, energy, and protein demands of early lactation and the hormonal fluxes of this stage of the reproductive cycle. In the parturient period, the concentration of glucocorticoids is increased. This means that leukocyte function is less effective, because expression of L-selectin and CD18 on neutrophils are down-regulated by glucocorticoids. This down-regulates adhesion between blood neutrophils and vascular endothelium and transendothelial migration of neutrophils. Neutrophils are also important in creating bystander injury when the products of neutrophil granules, such as superoxide anions and enzymes, are released during phagocytosis and with neutrophil destruction.

Natural killer cells use perforin to kill bacteria in a major histocompatibility complex (MHC) independent way, and so are part of the nonspecific defenses of the gland.

### 18.1.6.2.2

#### Adaptive Immunity

The humoral immune system operates in the mammary gland in several ways apart from the transfer of immunoglobulin in colostrum and during lactation. Antibody concentration in normal bovine milk is small, about 1 mg per milliliter, and includes IgG<sub>1</sub>, IgG<sub>2</sub>, IgM, and IgA. Most IgG is serum derived; IgG<sub>1</sub> is selectively transferred into mammary gland secretion and is the major immunoglobulin class in milk obtained from healthy mammary glands. IgG<sub>2</sub> is both serum derived and locally produced by resident plasma cells, especially in inflammation. IgA and IgM are synthesized locally in the stromal tissue of the acini of the mammary gland and may be part of the enteromammary link of the mucosal

## Pathologic Basis of Veterinary Disease, 4th Edition

immune system, whereby lymphocytes from gut-associated lymphoid tissue home to the reproductive tract. Local production is caused by stimulation of subepithelial lymphocytes.

Particulate antigens, such as bacteria, stimulate an antibody response in the mammary gland of the cow, whereas soluble antigens do not. In colostrum and in milk from inflamed mammary glands, antibody concentration approaches 50 mg per milliliter. Early in inflammation, IgG<sub>1</sub> and IgG<sub>2</sub> opsonize bacteria to enhance phagocytosis by macrophages, but later the importance of IgG<sub>2</sub> as an opsonin increases as neutrophils enter the gland. Neutrophils can transport IgG<sub>2</sub> to the mammary gland as they move to the site of inflammation. IgM also functions as an opsonin. IgA does not opsonize but could prevent bacterial adherence to epithelium, inhibit bacterial multiplication, neutralize leukocyte-inhibiting bacterial toxins, and agglutinate bacteria. Concentrations of immunoglobulin are reduced in the periparturient period and may contribute to the increased susceptibility of the gland to infection.

Cell-mediated immunity in the gland is stimulated in infectious disease. Interleukins from mammary gland macrophages stimulate the immune system by activating T and B lymphocytes. Only a few B lymphocytes are present in the normal mammary gland and milk. T lymphocytes in normal mammary gland tissue and milk of cows and pigs are mostly CD8<sup>+</sup>  $\alpha/\beta$ -T lymphocytes. The CD4<sup>+</sup>/CD8<sup>+</sup> ratio is <1, which is reversed from the ratio in blood. The mammary gland thus has selective lymphocyte

trafficking, favoring CD8<sup>+</sup> lymphocytes, which have either cytotoxic or suppressor function. T 1271

lymphocytes, which activate B lymphocytes, T lymphocytes, and macrophages, are underrepresented in 1272

normal mammary gland tissue and milk. CD8<sup>+</sup> T lymphocytes are found in the lactiferous duct and alveolar epithelium, whereas the lesser numbers of CD4<sup>+</sup> lymphocytes and B lymphocytes are in clusters in the connective tissues. In early lactation, the CD8<sup>+</sup> lymphocytes in milk function more as suppressor lymphocytes than cytotoxic lymphocytes, but the situation is reversed in mid and late lactation. Suppressor T lymphocytes control, modulate, or suppress the immune response, and cytotoxic T lymphocytes can act as scavengers, removing damaged mammary cells. CD4<sup>+</sup> (T helper [T<sub>H</sub>]) T lymphocytes predominate in goat mammary glands and in mastitis. In response to bacterial infection, an influx of CD4<sup>+</sup> T lymphocytes occurs in milk, and these lymphocytes eventually outnumber CD8<sup>+</sup> T lymphocytes. During the periparturient period, T<sub>H</sub>2 lymphocytes (cell-mediated response) secreting IL-4 and IL-10 predominate over T<sub>H</sub>1 lymphocytes (humoral-mediated response) secreting IL-2 and interferon- $\gamma$ . T lymphocytes may be cytotoxic, and they preferentially migrate to epithelial surfaces and can destroy altered epithelial cells.  $\gamma/\lambda$ -T lymphocytes are present in greater numbers in mammary gland secretions and parenchyma when compared with blood. The percentage of  $\gamma/\lambda$ -T lymphocytes of mammary parenchymal lymphocytes decreases in the postpartum period, a time of increased susceptibility of the mammary gland to disease, which suggests that  $\gamma/\lambda$ -T lymphocytes can be important in defense against infection.

### 18.2 DISEASES

#### 18.2.1 FEMALE REPRODUCTIVE SYSTEM

##### 18.2.1.1 ANOMALIES, INTERSEX, AND AMBIGUOUS DEVELOPMENT

Much of the development of the reproductive tract of domesticated animals is assumed from studies in human beings and a variety of animals, including laboratory rodents and the pig. It is easier to understand

## Pathologic Basis of Veterinary Disease, 4th Edition

developmental anomalies and neoplasia with an understanding of the basic components of sexual determination and differentiation. Finer details will be left to those who wish to study the incredibly intricate and fascinating world of embryology. There is a more pragmatic reason for examining embryology. Remembering all of the anomalies is a daunting task, but it is easier to learn the mechanisms of how they occur and if they are significant, and then establish how to manage them.

### 18.2.1.1.1 Normal Sexual Development

Early in fetal development, germ cells migrate from the yolk sac to the genital ridge. Without germ cells, the gonads do not develop, and aplasia is the result. The undifferentiated gonad then consists of the germ cells, mesenchymal cells, coelomic epithelial cells, and mesonephric epithelial cells. These form the four major cell types in the gonad: germ cells, supporting cells, steroid-producing cells, and unspecialized mesenchyme. Early in sexual differentiation, the embryo has a double set of ducts: the mesonephric ducts and tubules, and the paramesonephric (Müllerian) duct (Fig. 18-2). The tubular genitalia of the female develops from the paramesonephric ducts, and the mesonephric ducts disappear. The paramesonephric ducts are paired and attach to and join the urogenital sinus. They fuse to form the cranial vagina and the uterine body. The urogenital sinus forms the vulva and posterior part of the vagina. The external genital tubercle forms the clitoris. All stages of the development of the genitalia are under the control of genes and gene products; the female reproductive system is not a “default” system.

The sex of an individual can be defined at several different levels: genetic, chromosomal, gonadal, ductal, and phenotypic. The normal mammalian chromosomal sex is XX for female.

**Fig. 18-2 Schematic diagram of the normal components of the female reproductive system and the embryonic structures, especially the paramesonephric (Müllerian) duct and urogenital sinus and tubercle from which they were derived.** The paired paramesonephric ducts fuse to form the body of the uterus, cervix, and cranial vagina. The mesonephric tubules remain as the microscopic rete ovarii, but the mesonephric ducts usually regress completely.

1272

Major anomalies are those that result in dramatic abnormalities in sexual phenotype and usually result in infertility. Affected animals are phenotypically male, female, or ambiguous. The exact defect cannot be reliably guessed from phenotypic characteristics alone. Defining anomalies by the genotype, gonadal type, and phenotype is very simplistic as there are a large number of individual steps involved in sexual development and differentiation, and missing or changing one step can have major affects on subsequent differentiation. Common syndromes of abnormal sexual development are listed in [Table 18-1](#).

Anomalies of the reproductive tract come in many forms and have many causes. Abnormal location and size of the external genitalia creating phenotypic ambiguity is often an indication of a major anomaly. A basic definition of syndromes and identifying the underlying defect and pathogenesis requires initially an assessment of the genotype, gonadal type, and phenotype. Chromosomal analysis is required to determine the basic genotype. Gonadal anomalies are described at surgery and at necropsy, with histologic assessment being necessary to differentiate between rudimentary gonads, testis, ovary, and ovotestis, which is a combination of both male and female gonadal patterns in a single gonad. In phenotypic females, the lack of an estrus cycle, an enlarged clitoris, and/or an increased distance from the anus to vulva may indicate an abnormality.

**Table 18-1 Common Syndromes of Abnormal Sexual Development**

Syndrome	Species	Comments
Freemartinism	Bovine, ovine	Chimerism associated with twinning
XX sex reversal	American cocker spaniels	Autosomal recessive inheritance
XX sex reversal	Polled goats	Associated with the poll gene
Male feminization syndrome	Canine	Lack of testosterone receptors
Müllerian remnant syndrome	Miniature schnauzer	Complete internal female tubular genitalia in XY males
Failure of testicular descent	All species	Discussed under male genital system
Segmental aplasia	All species	Rare anomaly often missed at clinical examination
Gonadal hypoplasia	All species	Males especially

Some anomalies have their basis in genetics, others in gonadal development, and still others in the differentiation of the tubular genitalia. They can be insignificant or result in the animal being infertile or subfertile.

The terminology used to describe syndromes is variable and sometimes confusing. Sex reversal, hermaphroditism, pseudohermaphroditism, and feminization are examples. Often, descriptions of the phenotypic and gonadal anomalies are done without the benefit of genotype, so the conditions are incompletely described.

True hermaphrodites have both male and female gonads, usually ovotestes ([Fig. 18-3](#)). This is a very rare condition, and most have been XX hermaphrodites. Affected animals are most often seen as part of XX sex reversal. They are phenotypically female, with masculinization. XY or XX sex reversal results in a gonadal sex that is the opposite of the expected genotype. These animals are usually infertile and may have some characteristics of both males and females. For example, bucks can

## Pathologic Basis of Veterinary Disease, 4th Edition

---

develop mammary glands. Examples of XX sex reversal are seen in cocker spaniels and some other breeds as an autosomal recessive trait. In goats, it is associated with the polled gene. Confirmation of this syndrome requires genotyping as, in the case of goats, the presence of mammary development in bucks is not always an indication of XX sex reversal.

Pseudohermaphroditism is a mismatch between the tubular or external genitalia and the gonadal sex. 1273

Male pseudohermaphrodites (see [Chapter 19](#)) usually have an XY genotype, testes, but female tubular elements ([Fig. 18-4](#)). Miniature schnauzers with persistent Müllerian ducts have a complete Müllerian system with uterine tube, uterus, and cranial portion of the vagina. They lack Müllerian inhibitory substance or its receptor. Testicular feminization syndrome is a type of male pseudohermaphroditism, as the individuals lack testosterone or its receptors, and as such do not develop a typical male external genitalia. XX pseudohermaphrodites include freemartins and other chimeras. 1274

**Fig. 18-3 True hermaphrodite, reproductive tract, gilt.** An ovotestis is on the left and a testis on the right. Note the well-developed uterus, cervix, and vagina. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

**Fig. 18-4 Male pseudohermaphrodite, reproductive tract.** **A**, Pig. A testis and epididymis are present on each side. Note the well-developed uterus, cervix, and vagina. No ovarian tissue is present. **B**, Clitoral enlargement, dog. The clitoris protrudes between the labia of the vulva and is visible on the ventral floor of the vulva. Note the formation of a bifid scrotum ventral to the vulva. (**A** and **B**, Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

### 18.2.1.1.2.2

#### Chimerism

Animals that are chimeras or mosaics for the sex chromosomes have ambiguous reproductive organs (Fig. 18-5). Chimeras and mosaics have two or more cell types, each with a different chromosomal constitution. The cells of a chimera come from two different sources (such as from male and female members of a set of twins in the bovine freemartin), whereas the cells of a mosaic come from the same source.

The most common chimera in domestic animals is the freemartin calf (Fig. 18-5). Placental vascular anastomoses, which allow exchange of blood between fetuses, are a requirement for the occurrence of a freemartin. These anastomoses occur most often in the bovine species, and less frequently in other ruminants and pigs. The freemartin is the female of a set of male and female twins. The percentage of male cells in freemartins varies widely. Gene products from the cells of the male cause the differentiation of fetal Sertoli cells and seminiferous cordlike structures in the female twin's ovaries. The ovaries are small, ranging from organs with reduced number of or no germ cells, to organs partially converted to testes, or to organs composed entirely of structures resembling seminiferous tubules. The paramesonephric (Müllerian) duct derivatives vary from almost normal to cordlike structures, but communication is never made with the vagina. The vagina, vestibule, and vulva are hypoplastic. Seminal vesicles are always present; other mesonephric (Wolffian) structures are present

## Pathologic Basis of Veterinary Disease, 4th Edition

---

to varying degrees. Externally the animal appears female, but the vestibule and vagina are short, the vulva is hypoplastic, and the clitoris is enlarged. The male twin is minimally affected.

18.2.1.1.2.3

### Anomalies with normal sexual development

There are many different anomalies found in individuals that have a normal matching of genotypic, gonadal, and phenotypic sex organs. Although there are too many to list, most fit into the categories of failure of the normal maturation, hypoplasia, and aplasia. Because normal development requires such intricate timing of events—including regression of some parts, the joining of tubes and tubules, migration of components from one site to another, the interaction of genes, and hormones and local factors—it is no wonder there are a myriad of anomalies.

---

Segmental aplasia of the paramesonephric duct system can have a variety of forms. Little is known of the pathogenesis of segmental aplasia, apart from studies indicating a genetic basis in some breeds of cattle. Segmental aplasia of the paramesonephric duct system most often occurs in shorthorn cattle, in which it is associated with the recessive gene for white coat color. The simplest form is failure of the paramesonephric duct to make a proper connection with the urogenital sinus, leaving a persistent hymen, a membrane where the two precursor tissues join. A perforated hymen often persists and is of no clinical significance (Fig. 18-6). However, if the hymen is completely imperforated and there is no drainage, the vagina, cervix, and uterus fill with normal secretions. In the more severe forms, one or more segments of the vagina, cervix, uterine body, and uterine horns are absent or rudimentary. Generally the ovaries, uterine tubes, and most cranial parts of the uterine horns are present and normal, except that the horns can be distended by secretion.	1274 1275
---	--------------

**Fig. 18-5 Bovine freemartinism.** **A**, Phenotypically female, reproductive tract, cow. The freemartin is the female of a set of male and female twins. Freemartins are chimeras. There is a vulva and vagina with a prominent clitoris. The internal genitalia consist of bulbourethral and vesicular glands, ductus deferentes, and short incomplete segments of uterus. The gonads are testis with epididymides attached. This major anomaly renders the cow infertile. **B**, Placenta, twin fetuses. Placental vascular anastomoses, which allow exchange of blood between fetuses, are a requirement for the occurrence of a freemartin. These anastomoses occur most often in the bovine species. (**A** and **B**, Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Aplasia of a segment of the uterus (Fig. 18-7) can affect cattle. Prostaglandin can be synthesized and released from a uterine horn made blind by the absence of a segment, just as it would be produced by a normally connected uterine horn. In species such as the pig in which systemic transmission of  $\text{PGF}_{2\alpha}$  from the endometrium to the corpus luteum is important, prostaglandins from the blind uterine horn can have a lytic effect on the corpora lutea of pregnancy in the contralateral ovary. In species such as the cow, in which the local utero-ovarian pathway is important for luteolysis, the absence of a large segment of the uterus could result in an amount of  $\text{PGF}_{2\alpha}$  insufficient to cause regression of the corpus luteum. Even a small segment of uterine aplasia can have the same effect if the cranial segment becomes distended with fluid and does not synthesize prostaglandins. In the dog and cat, the uterus does not play a role in the regression of the corpus luteum.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Imperfect fusion of the paired paramesonephric ducts is a common cause of anomalies. Normally the two ducts unite first at the cloacal end to form the vagina and the process moves cranially to form the cervix and the uterine body. A double uterine body, called uterus didelphys, and a double cervix are normal structures at an early stage of development. Malformations due to imperfect fusion are most common in and adjacent to the cervix. They range from a dorsoventral fibrous band in the cranial vagina together with a normal cervix, to failure of fusion of the caudal cervix with bifurcation of the cervical canal, to complete duplication of the cervix and body of the uterus.

Hypoplasia (and its extreme, aplasia) of a portion of the reproductive tract apart from the tubular	1275
genitalia comes in many different degrees. Gonadal hypoplasia is common, especially in males, and	1276
these will be discussed in the relevant sections.	

---

**Fig. 18-6 Persistent hymen, vagina and vulva, bitch.** The membrane (*arrow*) partially separates the vestibule from the vagina and is just cranial to the urethral opening. This minor anomaly is of little consequence and does not interfere with coitus or parturition. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

## Pathologic Basis of Veterinary Disease, 4th Edition

18.2.1.1.3

### Minor Anomalies

Minor or incidental anomalies are myriad in the reproductive tract. The same factors influencing the development of major anomalies in animals with normal sexual differentiation are at work here too. Minor anomalies are those curiosities that are incidental and are of no clinical significance apart from being mistaken for lesions that do cause infertility, subfertility, or are life threatening. Foremost of these are the numerous cysts and tubular remnants that can be found in many individuals. The so-called paraovarian cysts are extremely common and can be confused with cystic neoplasia. They can be derived from paramesonephric ducts, mesonephric ducts, and mesonephric tubules. [Table 18-2](#) lists the location and names of common incidental cystic anomalies. They will be discussed in more detail later.

**Fig. 18-7 Segmental aplasia of a uterine horn, uterus, pig.** The right uterine horn is completely missing. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

Cysts of the reproductive tract not derived from embryonic elements are called inclusion cysts. One of the more common types is the serosal inclusion cyst of the uterus in bitches ([Fig. 18-8](#)). It is assumed to arise from small groups of mesothelial cells that get trapped beneath the serosal surface during involution of the uterus. These grapelike clusters of semitransparent thin-walled cysts are found on the serosal surface of the uterus. Subsequent distention and enlargement result in numerous cysts developing.

18.2.1.1.4

### Common Syndromes

Many of the commonly seen syndromes of sexual development were mentioned earlier in the relevant sections, but they are combined with those of the male reproductive system and listed in [Table 18-1](#).

## Pathologic Basis of Veterinary Disease, 4th Edition

### 18.2.1.2 OVARY

#### 18.2.1.2.1 Developmental Anomalies

Occasionally, agenesis from unknown cause involves one or both ovaries. The reproductive tract can be absent as part of the defect. In cases of bilateral agenesis, the tubular genitalia remain infantile. Duplication of an ovary is a rare anomaly, arising by two different mechanisms: originating separately or splitting from an already developing ovary. The latter type, an accessory ovary, is close to the normally located organ and is usually connected to it. This anomaly is an uncommon cause of ovarian remnant syndrome. Ovarian remnant syndrome is a syndrome that develops in previously spayed cats and dogs that come into heat (estrus) again. Failure of complete surgical removal at the time of spaying is the usual cause.

Hypoplasia of the ovaries occurs most commonly in cows and to a lesser extent in other species. It is usually bilateral but nonsymmetric. The affected ovaries are small and lack follicles or surface scars from ovulation. Microscopically, cortical stroma and ova are absent or poorly developed. The tract remains infantile after puberty. Other causes of an infantile reproductive tract are malnutrition or other forms of debility. Ovaries in these animals, however, have numerous primordial follicles and can respond to gonadotropic hormones after removal of the debilitating factor.

1276

1277

Table 18-2 Cysts of the Female Reproductive Tract by Location

Cyst	Origin	Species
<b>Intraovarian</b>	Cystic rete ovarii	Mesonephric tubule
	Inclusion cyst	Ovarian epithelium
	Subsurface epithelial structure	Normal invagination of ovarian epithelium
	Cystic follicles	Graafian follicle
	Anovulatory cyst	Graafian follicle
	Luteal cyst	Graafian follicle
	Cystic corpus luteum	Graafian follicle
	Cystadenoma, cystadenocarcinoma	Rete ovarii, subsurface epithelial structure, surface epithelium
<b>Paraovarian</b>	Accessory uterine tube (hydatid of Morgagni)	Paramesonephric duct
	Fimbrial cyst	Paramesonephric duct
	Bursal cyst	Ovarian bursa
	Mesonephric duct cysts	Mesonephric ducts
	Hydrosalpinx	Obstruction of uterine tube
<b>Uterine</b>	Serosal inclusion cyst	Serosal mesothelium
	Adenomyosis	Endometrium
	Cystic endometrial hyperplasia	Endometrium/endometritis
<b>Vaginal</b>	Mesonephric (Gartner's) ducts	Mesonephric duct remnants
<b>Vestibular</b>	Cystic vestibular (Bartholin's) gland	Inflammation of vestibular glands

**Fig. 18-8 Uterine serosal inclusion cysts, reproductive tract, bitch.** The cysts projecting from the serosal surface of the uterus are believed to arise from mesothelial cells trapped within serosal connective tissue. These cysts are an incidental finding at ovariectomy. Note that there are also multiple thin-walled cysts around the right ovary. These cysts are remnants of embryonal ducts and are called paraovarian cysts. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

Hypoplasia caused by genetic and chromosomal abnormalities has been reported. Ovarian hypoplasia occurs in Swedish Highland cattle as an autosomal recessive trait with incomplete penetrance. The ovarian defect is either unilateral or bilateral. The number of primordial follicles and the proportion of Graafian follicles are less than normal. Luteinization tends to occur without ovulation. Ovarian hypoplasia has been associated with cytogenetic anomalies such as XXX chromosomes in the mare and cow and XO chromosomes in the mare. The latter type is similar to the XO disease in human females,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

called Turner's syndrome, with such features as small stature, lack of uterine cyclic activity, and underdevelopment of the endometrium. The fetal gonad is normal, but the adult ovary has no follicles.

Vascular hamartomas of the ovary are incidental findings in the cow, sow, and mare. They occur as a dark red mass on the surface of the ovary and consist of connective tissue and vascular channels lined by mature endothelial cells.

Cysts in and around the ovary are common findings in many species, particularly in dogs and cats during ovariohysterectomy (Table 18-2). They are of two types: those within the ovary and those outside the ovary. The latter cysts are grouped as paraovarian cysts, and they arise from either paramesonephric ducts or the mesonephric tubules and ducts. Location of the cyst is the most reliable method of differentiating them. Sometimes, histologic similarities with a normal uterus allows identification of those cysts that are of paramesonephric ductal origin.

Cystic remnants of the paramesonephric ducts include the fimbrial cyst and the cystic accessory tube. 1277

This latter cyst is common in the mare and is called the hydatid of Morgagni (Fig. 18-9). They can be several centimeters in diameter. There are many cysts that arise from mesonephric remnants, and some develop in and around the ovary from mesonephric tubules. One of the most common in the dog and cat is the cystic rete ovarii (Fig. 18-10). They can reach several centimeters in diameter. Cystic rete ovarii expand into the ovarian stroma, as they are located in the ovarian hilus. They are lined by ciliated columnar to flattened epithelium. Cystic ovarian neoplasms are an important differential diagnosis of cysts of or near the ovary. Histologic examination may be required to differentiate them. They are described under Neoplasms. Other cysts of the ovary are derived from the ovarian surface or from the Graafian follicle and will be described under Lesions of the Ovarian Follicles. 1278

**Fig. 18-9 Hydatid of Morgagni, ovary, mare.** This cystic structure is located in the fimbria, adjacent to the ovary. They are very common in mares and are cystic remnants of paramesonephric ducts. (Courtesy Ontario Veterinary College, University of Guelph.)

**Fig. 18-10 Multiple cystic rete ovarii, ovary, bitch.** Note the multiple cysts within the ovary at the hilus. They are incidental findings in bitches and are of little consequence. They develop from the rete (mesonephric tubules) of the ovary and become cystically distended. In cats, they can be unilocular and very large and cause pressure atrophy of the ovary. They must be differentiated from cystadenomas and cystadenocarcinomas, histologically. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

### 18.2.1.2.2

#### Acquired Ovarian Lesions

Oophoritis, or inflammation of the ovary, is rare in domestic animals. Experimentally, infectious bovine rhinotracheitis virus (bovine herpesvirus 1[BHV-1]) can induce necrotizing oophoritis in the postestrus cow subsequent to viremia. The corpus luteum is hemorrhagic, and thick, cloudy fibrinous fluid fills some follicles. Microscopically the lesions in the corpus luteum range from focal necrosis and infiltration of mononuclear cells to diffuse hemorrhage and necrosis. Most affected ovaries also have necrotic follicles and diffuse mononuclear cell infiltrates in the stroma. Bovine viral diarrhea (BVD) virus, a vertically and horizontally transmitted virus responsible for mild to fatal enteric disease and reproductive failure, can localize in bovine oocytes and cumulus cells and cause chronic oophoritis. Infection of ovarian oocytes with BVD virus is one of several possible routes of transmission of the virus from cow to fetus. Bacterial oophoritis occasionally is found in cats and dogs. In cats, it must be differentiated from feline infectious peritonitis. The inflammation is around the ovary and within the uterine tube, suggesting that the causative bacteria ascended from the uterus.

Ovarian bursal adhesions vary from thin bands to large sheets of fibrous tissue binding the walls together or crossing the cavity of the ovarian bursa, a peritoneal pouch formed around the ovary by the broad ligament and the mesosalpinx. The lesion is often bilateral in cows and could result from an ascending

## Pathologic Basis of Veterinary Disease, 4th Edition

---

uterine infection that follows a retained placenta after parturition. Physical trauma from manipulations of the ovary is another possible cause; bursal adhesions are common in beef heifers. Adhesions can obstruct or cause retention of fluids in the bursa and result in a cystic bursa.

Epithelial inclusion cysts are common in mares, in which they can be a cause of infertility (Table 18-2). It is believed that epithelium from the surface of the ovary becomes pinched off and embedded in the stroma during ovulation. This epithelium produces a fluid that causes the structure to enlarge and eventually reach several centimeters in diameter. They are identical in appearance to large follicles, and they do not appear and disappear as follicles should; histologic assessment is necessary for accurate diagnosis. Their size and number may block ovulation. Similar cysts in other species and cysts of the subsurface epithelial structures of the bitch are usually small and incidental.

1278

18.2.1.2.3

### Lesions of the Ovarian Follicles

1279

Hemorrhage into follicles is sometimes present in calves, and hemorrhages into cystic follicles happen occasionally in the bitch. A small amount of hemorrhage is normal at the time of ovulation in all species. The mare is an exception because normally much blood is present in the cavity of the follicle, forming the corpus hemorrhagicum. In rare cases, the hemorrhage can be extensive enough to form an ovarian hematoma or even hemoperitoneum can occur. If it extends through the ovulation fossa, the corpus luteum can be external to the ovarian capsule. In the mare and cow, a focal area of serositis is detectable at the point of ovulation. Progression through a fibrinous to a fibrous stage is rapid, and an “ovulation tag” is formed. The manual expression of a persistent corpus luteum in the cow sometimes is followed by severe hemorrhage. Organization of the blood clot can result in adhesions between the ovary and adjacent structures, such as fimbriae of the uterine tube or ovarian bursa, and cause infertility.

Atretic follicles are those that become arrested at any stage of development and then regress. Atretic follicles are, in most cases, normal. In any estrus cycle, only one or a small number of follicles is destined to mature, whereas the others undergo atresia at various stages of maturation. A similar process occurs in seasonal anestrus and in all domestic species during pregnancy, except for the mare. Follicular atresia is considered abnormal when it is a part of any disease process that interferes with the release of, or the pituitary response to, GnRH. Development of the follicle can be arrested at any stage, and after an undetermined amount of time, it degenerates. The ovum undergoes apoptosis first; then the granulosa cells become pyknotic, vacuolated, and desquamate. The follicle either persists as a cyst with a partial thin lining of granulosa cells or is infiltrated by macrophages, theca cells, and fibrous connective tissue, eventually becoming a small scar.

Cystic ovarian (Graafian) follicles, or follicular cysts, are important in cows and sows. The disease in cows is called cystic ovarian degeneration (COD). In dairy cows, the prolongation of the postpartum interval to first estrus (days-open) is the main consequence of cystic follicles. Ovulation does not occur. These cysts probably develop because of an abnormality of the hypothalamo-hypophyseal-ovarian axis that causes a deficiency of LH or of the LH receptor in the ovary, although the mechanism is not defined. Cystic ovarian degeneration is treated with GnRH (that causes release of LH in the pituitary) and with chorionic gonadotrophin (high in LH). Evidence is available that stress may be involved wherein adrenocorticotrophic hormone (ACTH) or cortisol inhibits GnRH release from the hypothalamus and prevents up-regulation of LH receptors in the ovary. Higher concentrations of progesterone can have a similar effect. The end result is an inadequate LH surge and failure of ovulation. In a similar way, postpartum uterine infection can cause cystic ovaries in dairy cows.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Cystic ovaries have been linked with the recovery of *Escherichia coli* from the uterus and increased concentrations of serum PGF<sub>2α</sub> metabolites and cortisol. Because of these findings, it has been proposed that bacterial endotoxins, or the prostaglandins produced because of damage caused by endotoxins, stimulate the adrenal cortical secretion of cortisol; cortisol excess suppresses the preovulatory release of LH, resulting in the development of cysts. Bovine cystic follicles are 2.5 cm or more in diameter (Fig. 18-11) and persist for 10 or more days without the formation of a corpus luteum. Cystic follicles were common lesions in a large slaughterhouse survey of beef heifers.

An anovulatory luteinized cyst is likely caused by delayed or insufficient release of LH and is therefore part of COD (Table 18-2). It occurs in cows and sows more often than in other species. Ovulation does not occur. The cystic cavity is lined by fibrous tissue, surrounded by an adjacent zone of luteinized theca cells. Cystic follicles and luteinized cysts can occur in the same ovary. The extent of luteinization that must occur in a cystic follicle to justify its designation as a luteal cyst has not been defined.

Cystic corpus luteum is of uncertain pathogenesis. In cows, it must be distinguished from anovulatory luteinized cyst and from the small central cyst that can occur normally in a corpus luteum. Ovulation occurs and a large irregular cyst develops (Fig. 18-12), but without interfering with the length of the estrous cycle. It has been suggested that at least in sows the cysts found in ovaries are different stages of the same aberration. The morphologic form, whether an ovulated or unovulated follicle or a corpus luteum, is determined by the stage at which the physiologic process became abnormal.

1279

1280

**Fig. 18-11 Cystic Graafian follicle, ovary, cow (also called follicular cysts).** Follicular cysts are larger than normal follicles and usually greater than 2.5 cm in diameter. They are the macroscopic lesions of cystic ovarian disease in the cow. They arise when ovulation of a normal follicle does not occur. (Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph.)

Fig. 18-12 **Cystic corpus luteum, ovary, cow.** A cystic corpus luteum is a normal corpus luteum complete with an ovulation papilla and a prominent cystic center. There is also a normal Graafian follicle (*left*) present. (Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph.)

Supernumerary follicles are induced in bovine ovaries by chorionic gonadotropin or follicle-stimulating hormone used in doses to cause superovulation in preparation for embryo transfer. In these cows, it is not unusual for more than a dozen well-developed ovarian follicles or corpora lutea of the same age to be present.

### 18.2.1.2.4

#### Neoplasms

There are three main groups of primary ovarian neoplasia in domesticated animals: germ cell, sex-cord stromal, and epithelial neoplasms. These represent the major histogenic origins of the cells of the ovary. Little is known of ovarian carcinogenesis, although there is evidence in human beings that estrogen (and the lack of pregnancy) may be involved.

### 18.2.1.2.4.1

#### Germ cell neoplasms

It would be expected that neoplasms arising from germ cells could differentiate along either embryonic or extraembryonic lines and could be benign or malignant or undifferentiated. The great majority of neoplasms of germ cells are benign and undifferentiated (dysgerminoma) or benign with somatic differentiation (teratoma).

Dysgerminoma is a rare neoplasm of bitches, sows, cows, and mares and is composed of cells resembling primitive germ cells. The neoplasm is usually a solid lobulated mass with areas of hemorrhage and necrosis. It is analogous to seminoma in the male. Mitotic rate is high, but metastases are rare.

**Fig. 18-13 Ovarian teratoma, ovary, bitch.** These tumors have cells derived from all three germ cell lines: ectodermal (epithelium, including neuroepithelium), mesodermal (mesenchymal tissue), and endodermal (intestine and respiratory tissues). The most common tissues seen macroscopically include hair, cartilage, and bone. This teratoma was 30 cm in diameter and surrounded by a bursa, but residual ovarian tissue was not found. Hair and bone are the main structures visible. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Ovarian teratomas are rare, usually well differentiated, and benign. They arise from totipotential primordial germ cells and have disorganized elements of at least two of the three embryonic germ layers. Skin is often a significant component (Fig. 18-13). Malignant teratomas occur less often, except in the bitch.

### 18.2.1.2.4.2

#### Gonadal stromal neoplasms

Granulosa cell neoplasms are the most common ovarian neoplasms in large animals. They are unilateral, smooth surfaced, and round and can be 20 to 30 cm in diameter. They can be solid, cystic, or polycystic (Fig. 18-14, A and B). The cysts can vary from microscopic size to several centimeters in diameter. Often the fluid within the cysts is red-brown. Microscopically the granulosa cells are not different from normal granulosa cells and often are arranged as they would be in normal Graafian follicles, that is, in single or multiple rows of round to columnar cells lining fluid-filled spaces (Fig. 18-14, C). In less differentiated areas, the neoplastic cells are arranged in sheets. Sometimes, especially in queens, Call-Exner bodies are present in the fluid. These bodies are rosettes of granulosa cells, some containing an eosinophilic body in the central space. The stroma can be sparse or plentiful; if the stroma predominates, the neoplasm is a thecoma. The cytoplasm of some thecoma cells contains

## Pathologic Basis of Veterinary Disease, 4th Edition

---

lipid droplets. Areas of luteinization in granulosa-theca cell neoplasms are not uncommon, but	1280
luteomas, neoplasms with a uniform population of luteinized cells, are rare. Luteomas can probably	1281
develop from either granulosa or theca cells. Granulosa cell neoplasms are often malignant in the	
queen and sometimes in the bitch, but in the cow and mare, sex cord stromal neoplasms are usually	
benign. Many stromal neoplasms produce estrogens or androgens. The mare can have signs of	
anestrus, nymphomania, or stallion-like behavior; the bitch is likely to have prolonged estrus and may	
develop pyometra.	

Fig. 18-14 **Granulosa cell tumor, ovary, cow.** **A**, This large, lobulated neoplasm has obliterated the normal structure of the ovary. They can be solid (as in this case) or multicystic. **B**, Multiple fluid-filled cysts and solid areas have caused the dramatic ovarian enlargement. Granulosa cell tumors are part of the group of neoplasms known as gonadal stromal tumors. **C**, This granulosa cell tumor has solid and cystic regions. The cysts are lined by cells that resemble granulosa cells of the follicle. H&E stain. 18.2.1.2.4.3

### Epithelial neoplasms

The ovaries are covered by coelomic epithelium, the same layer of tissue that invaginates in early fetal life to form the lining of the reproductive tract. Neoplasms of the ovarian surface epithelium can thus resemble the several neoplastic types of the endometrium. The serous type is the only important one in animals. Serous papillary cystadenoma and cystadenocarcinoma occur commonly in the bitch (Fig. 18-15, A). The other main type is the cystadenoma and cyst adenocarcinoma. They originate from the surface epithelium or from subsurface rests within the ovary or from the rete ovarii. The neoplasms are frequently bilateral, with a shaggy surface and up to 10 cm in diameter. Malignant forms spread over the peritoneal surface by both lateral extension and seeding (Fig. 18-15, C). Ascites results either from obstruction of the diaphragmatic lymph vessels, which reabsorb peritoneal fluid, or from excess fluid secretion by the neoplasm.

18.2.1.3

### UTERINE TUBES

Most lesions of the uterine tubes are either incidental or secondary to lesions elsewhere in the reproductive tract. In dogs and cats, commonly seen lesions of the uterine tubes are unlikely to affect reproductive performance. Lesions commonly encountered in dogs and cats are duct remnants in the mesosalpinx, more often of mesonephric ductal (simple tubular structures lined by low columnar to cuboidal cells) than paramesonephric ductal (lined by a folded mucosa similar to the uterine tube mucosa) origin.

Congenital or acquired hydrosalpinx, distention of the uterine tubes by clear fluid, is caused by mechanical or functional obstruction of the lumen. The obstruction can be at either end of the uterine tube. The distention can be uniform or irregular; the wall is thin, and the tube increases in length and tortuosity. Multiloculated cysts are numerous in the mucosa. The congenital type result from segmental aplasia of the uterine tube, as is present in freemartins, or more likely to segmental aplasia of the horn of the uterus. The acquired type is secondary to trauma or chronic inflammation; acute inflammation will cause pyosalpinx rather than hydrosalpinx. Trauma by manual interference with a corpus luteum in cows can cause an organizing hematoma about the uterine tube, resulting in obstruction by external pressure. This same manipulation can force inflammatory exudate from the uterus into the uterine tube, causing inflammation of tubular mucosa and obstruction of the lumen. Inflammatory exudate can be forced manually or under the pressure of therapeutic uterine infusion, not only into the uterine tube but also into the ovarian bursa, where the ensuing inflammation can result in fibrous bands that compress the uterine tube. Hydrosalpinx, or a bacteriologically sterile pyosalpinx, is one of the most common causes of sterility in pigs. It occurs almost exclusively in nulliparous animals and is almost always bilateral. The cause is unknown, but some evidence points to obstruction by embryonal rests of the mesonephric duct.

1281

1282

**Fig. 18-15 Papillary ovarian carcinoma, ovary, bitch.** **A**, Both ovaries are enlarged by neoplastic epithelium that has formed papillary structures that give the masses a shaggy outer surface. These neoplasms are often malignant and bilateral, and they seed the abdomen, producing carcinomatosis. **B**, Neoplastic epithelial cells are arranged in cords and papillae, are pleomorphic, and have many mitoses. H&E stain. **C**, This papillary carcinoma has seeded the abdominal cavity, implanted on the peritoneum, invaded into the muscle of the diaphragm, and is in subserosal lymphatics adjacent to the diaphragmatic skeletal muscle (*right*) H&E stain. McEntee, Reproductive Pathology Collection, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Salpingitis is uncommon in domestic species and results from spread of infection from the uterus to the uterine tubes; it is often bilateral. Generally, gross lesions are few, except perhaps for some hyperemia and thickening of the mucosa and small amounts of luminal exudate. Perioophoritis is a likely sequela and can cause infertility. Microscopically the inflammation ranges from mild to severe and from acute to chronic. Early mild lesions are loss of cilia and desquamation of epithelial cells at the tips of the mucosal folds. When severe, salpingitis involves other parts of the mucosa and sometimes the muscle layer. Exudate is present in the lumen. With time, adhesions form between the denuded areas and adjacent mucosa becomes cystic, reepithelializes, or is replaced by granulation tissue.

Pyosalpinx has similar pathogenetic events to salpingitis but is more severe, as suppurative exudate accumulates in the lumen. Obstruction of the lumen occurs, likely secondary to accumulation of exudate, or to scarring. Neutrophils predominate and form large lakes in the lumen or in mucosal cysts derived from the glands of the tube. The epithelium is damaged by the causative agent and by the products of neutrophilic granules that are released during phagocytosis and death, with the result that there is erosion and subsequent granulation, or the epithelium undergoes squamous metaplasia.

Ectopic pregnancy, as occurs in human beings, does not occur in domesticated mammals. Traumatic rupture of the pregnant uterus and release of the fetus into the abdomen is the usual cause of so-called ectopic pregnancy in dogs and cats.

### 18.2.1.4 UTERUS

#### 18.2.1.4.1 Inflammation

Uterine disease is a significant cause of infertility and, in some cases, mortality. Foremost of these are inflammatory diseases, usually the result of contamination of the uterus with bacteria.

1282

Most uterine infections are the result of ascending infection that arises when the cervix is open—at estrus, parturition, or postpartum involution. Occasionally, infection can occur from a descending spread or via the hematogenous route, particularly in pregnancy when the uteroplacental interface is the site for preferential localization of organisms. It is assumed that the placenta is the target and the endometrium is secondarily affected, but the interface of the two systems is an area where a unique environment exists that is suitable for many infectious agents to multiply. Resistance of the uterus to infection is influenced by physical factors, the hormonal environment, and the humoral and cellular immune mechanisms as discussed previously.

1283

Endometritis is inflammation limited to the endometrium, usually due to seminal fluid and bacterial infection in nonpregnant animals, and in cows, herpesviral infections are the usual causes. In pregnancy, organisms that cause placentitis, fetal infection, and abortion, in most cases, also spread and cause inflammation of the endometrium. Postpartum endometritis occurs to some extent even after a normal pregnancy and parturition, but endometritis is especially common and more severe following an abnormal parturition. Lochia, the fluid and debris that is discharged from the uterus for a short time after parturition, is an excellent nutrient medium for bacterial growth.

Mild cases of acute endometritis are not detected grossly. It can induce cystic endometrial hyperplasia in dogs and cats. In more severe cases of acute endometritis, the mucosa is swollen and has a rough surface, often with adherent shreds of fibrin and necrotic debris. At microscopic examination, a few to many neutrophils are found in the stroma and in the glands, with a range of surface changes from

## Pathologic Basis of Veterinary Disease, 4th Edition

---

desquamation of a few surface epithelial cells to severe necrosis of the endometrium. Mild lesions resolve completely or incompletely with residual changes of cystic glands and periglandular fibrosis. Severe acute endometritis often becomes chronic, and the necrotic endometrium is replaced by granulation tissue devoid of glands, and ultimately this matures to form fibrous tissue. Acute endometritis can stimulate the synthesis of  $\text{PGF}_{2\alpha}$  in large animals that have had 4 or 5 days of progesterone priming, causing premature regression of the corpus luteum and shortening of the estrous cycle. The loss of endometrium in chronic endometritis can result in reduced production of  $\text{PGF}_{2\alpha}$ , and this decrease in  $\text{PGF}_{2\alpha}$ , especially in the mare and the cow, results in a persistent corpus luteum.

In the mare, endometrial biopsy is used as a breeding management tool because the severity of endometritis is correlated directly with the inability of the uterus to carry a fetus to term. To give a prognosis based on the features of the endometrium, focal and diffuse inflammatory cell infiltration of the stroma, contents of the glands, and frequency and severity of periglandular fibrosis are scored (Fig. 18-16). The endometrium of individual mares is categorized as predicted high, reduced, or low likelihood of the animal completing pregnancy.

Persistent mating-induced endometritis is a problem in mares. Affected animals are unable to resolve the acute endometritis that usually follows mating. The inflammation that occurs at mating, presumably because of the local effects of seminal fluid, lasts 24 to 36 hours in normal mares. Those mares that fail to clear this inflammation accumulate fluid in the uterus, and edema also persists. This persistence is now believed to be an inability of some mares to adequately clear uterine contents (including seminal fluids) after mating because of a defect in uterine contractility. There appears to be an intrinsic dysfunction in myometrial contraction, and accumulation of nitric oxide and its absorption may interfere with uterine myoelectrical activity. Greater susceptibility is believed to occur with repeated pregnancies, loss of body condition, and genetics. The position of the uterus plays a role, and normal mares have a more horizontal uterus than the more drooped or vertical orientation of susceptible mares.

Metritis is inflammation of all layers of the uterine wall. It is a more severe and advanced form of endometritis. In the acute stage, in addition to endometritis, the serosa is dull, finely granular, and has petechial hemorrhages and fine adhering strands of fibrin. Microscopically the subserosal tissue, muscle layers, and the endometrium are edematous and infiltrated by neutrophils.

1283

1284

**Fig. 18-16 Endometrial fibrosis, endometrial biopsy, mare.** Fibrosis from endometrial inflammation and edema results in endometrial glands forming nests (*right*) and cysts (*left*). This fibrosis results in reduced fertility due to a lack of attachment of the conceptus, or a failure of formation of normal microcotyledons and a reduced placental area. H&E stain. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Pyometra occurs as a sequela to endometritis or metritis. It is an acute or chronic infection of the uterus with accumulation of pus in the lumen ([Fig. 18-17](#)). The closure of the cervix is not always complete, and some discharge occurs. In some instances, the obstruction of the cervix is mechanical, but most cases are caused by a functional obstruction of the cervix, just as with diestrus, and is under the influence of progesterone produced by a retained corpus luteum. In the cow, the persistence of the corpus luteum is usually secondary to a pathologic process in the uterus. In the bitch and queen, most cases of pyometra follow endometritis (see the section on cystic endometrial hyperplasia later in this chapter) ([Fig. 18-18, A and B](#)). The color and consistency of the exudates vary with the infecting bacteria. Exudate is viscid and brown with *Escherichia coli* infection and creamy yellow with streptococcal infection. The uterus can be greatly distended, but not necessarily uniformly. Grossly, necrotic, ulcerated, and hemorrhagic areas are present in the uterine mucosa, along with dry, white, thickened, finely cystic areas. Microscopically the dry white areas have changes of hyperplasia and squamous metaplasia of surface epithelium, a common occurrence in chronic inflammation of any mucous membrane. The cystic areas are caused by cystic endometrial hyperplasia ([Fig. 18-19](#)). Lesions outside the genital tract such as bone marrow depression, widespread extramedullary hematopoiesis, and immune complex glomerulopathy are common in the bitch.

Fig. 18-17 **Pyometra, uterus, cow.** The uterus is distended and filled with foul-smelling dark brown fluid. The endometrium was red-black and dull, indicating an endometritis secondary to bacterial infection. This cow developed a severe pyometra immediately after calving. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

**Fig. 18-18 Metritis-pyometra-endometrial hyperplasia, uterus, bitch.**

**A**, Pyometra occurs several weeks after estrus. Bacteria grow in the uterus and induce a suppurative response. The uterus fills with pus and is distended. **B**, Endometritis and pyometra. There are large numbers of lymphocytes and plasma cells in the endometrial stroma. The surface epithelium is hyperplastic and papillary. The luminal epithelial cells are highly vacuolated. Pus in the lumen of the uterus was removed during processing of the histologic section. H&E stain. (**A**, Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

1284

18.2.1.4.2

### Noninflammatory Diseases

1285

Torsion of the uterus occurs in pregnant animals, mainly in the cow. To a lesser extent, it occurs in the pregnant bitch and queen (Fig. 18-20) and when the uterus is enlarged by pyometra (accumulation of pus in the uterine lumen) or mucometra (accumulation of mucus in the uterine lumen). The mesovarium is a fixed point in both the cow and the bitch, with the other fixed point influenced by the length of the horns and the presence and rigidity of the ligament between the horns. The rotation is around the mesometrium and tends to occur at the level of the cervix in the cow and the junction of the uterine horn and body in the bitch and queen. The result of torsion is circulatory compromise and venous infarction. The veins, being of a lower pressure and thinner walled, are compressed and occluded before the arteries. The uterine wall and placenta become congested and edematous. The fetus dies and mummifies or putrefies if the cervix is open enough to allow the entrance of bacteria or fungi to colonize the fetus. The uterine wall is friable and prone to rupture. Rupture of the uterus is also likely in severe dystocia and during

## Pathologic Basis of Veterinary Disease, 4th Edition

---

treatment of uterine diseases by infusion of drugs and fluids. Rupture can be incomplete, involving just the mucosa, or complete. The torsion and dystocia-related ruptures are likely to be in the caudal part of the uterus and are often fatal because of hemorrhage or infection. The rupture that follows overvigorous infusion of medications into the uterus occurs at the lesser curvature of a horn, dissects beneath the serosa and into the mesometrium, and results in perimetritis.

**Fig. 18-19 Cystic endometrial hyperplasia, uterus, bitch.** Note the cysts in the mucosa of the endometrium. This change occurs under the influence of progesterone after estrus. Cystic hyperplasia may provide a suitable environment for bacteria to grow and cause pyometra, or alternatively, cystic hyperplasia may be secondary to uterine infection and endometritis. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 18-20 Uterine torsion, cat.** The dark red black structure (*bottom center*) is a twisted uterine horn that contains a fetus. Its color is the result of venous infarction. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Prolapse of the uterus is important in the ewe, cow, and sow after parturition. Factors that cause uterine inertia, such as prolonged dystocia, hypocalcemia, and ingestion of estrogenic plants, usually contribute to prolapse of the uterus. A flaccid uterus and excessive straining are predisposing conditions. The anatomic structures that are prolapsed can be restricted to the previously pregnant horn, cervix, or vagina or can include all of the uterus, the bladder, and sometimes some of the small intestine. As the structures prolapse, there is vascular compromise, and congestion and edema result (Fig. 18-21). Constriction by the vaginal and vulval tissues exacerbates this, and as edema develops, the tissues exposed to the outside environment continue to swell and hang down. They dry and become traumatized, further exacerbating the swelling. Continued straining and the effects of gravity on the prolapsed tissues continue to contribute to stretching of internal structures, such as ligaments and blood vessels. Hemorrhage and shock can cause death; even if the uterus is returned to its normal anatomic position in the abdominal cavity via palpation and the animal survives, the intervening drying, trauma, venous infarction, and infection that occur will prevent future fertility.

Subinvolution of placental sites is the longer than normal persistence of placental sites in the uterus after parturition in the bitch, beyond the normal 12 to 15 weeks. In the normal placenta, trophoblasts are found in the endometrium and around the small blood vessels of the myometrium, but they rapidly degenerate in the postpartum period. In the bitch, subinvolution of placental sites is characterized clinically by an excessive bloody vaginal discharge that lasts for weeks or months after delivery instead of the normal 1 to 6 weeks. Grossly, subinvolved placental sites are about twice the size of normal sites for the same time after parturition, but their appearance is identical to normal except that fibrin adherent to the site is more prominent (Fig. 18-22). As such, multiple segmental thickenings of the walls of the uterine horns are identifiable from the serosal surface. The luminal surface of each site is a raised, rough, ragged, gray-to-brown plaque of hemorrhage and fibrin. Microscopically the superficial part of the plaque near the lumen consists of cell debris, hematoma, thrombus, and regenerating endometrium. In the deeper part

1285

1286

## Pathologic Basis of Veterinary Disease, 4th Edition

---

of the site, the changes are collagen deposition, hemorrhage, distention, and decreased density of endometrial glands. Trophoblast-like cells are more numerous in subinvolution sites than in normal placental sites and are abundant at the base of the deposited collagen; these cells can invade the myometrium and penetrate the full thickness of the wall and perforate the uterus. Because affected animals have a bloody discharge, anemia can result, and those dogs with coagulation disorders, such as von Willebrand's disease, can exsanguinate. The uterus is prone to develop postpartum infection and endometritis, and open pyometra can occur or worsen.

**Fig. 18-21 Uterine prolapse, cow.** The uterus, cervix, and part of the vagina have prolapsed. The uterus has become swollen from dependent edema and from reduced venous outflow. The mucosae are exteriorized and exposed to the environment, and thus they have become dehydrated and traumatized. (Courtesy Dr. C. Wallace, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 18-22 Subinvolution of placental sites, uterus, bitch. A,** Incompletely involuted placental sites. The red transverse stripes are placental sites with hemorrhage, fibrin, and necrotic debris. They are larger than normal sites for the same stage after parturition and remain long after normal sites would have disappeared (12 to 15 weeks postpartum). **B,** Transverse section of the uterus at a subinvolved placental site. The two pink outer layers are normal myometrium and underlying endometrial stroma. Most of the distended lumen is filled with large irregularly sized clots of blood, fibrin, and necrotic debris around which are endometrial epithelium and trophoblastic cells. H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Pseudopregnancy is an exaggerated form of a normal physiologic process. Every entire female dog has a prolonged luteal phase of estrus, and this has been referred to as covert pseudopregnancy or physiologic pseudopregnancy. Some dogs, especially of the toy breeds, develop this exaggerated reaction, and prolactin or its receptors play a role, but it is poorly understood. The presence of progesterone is permissive of the changes that occur. Overtly pseudopregnant dogs either have an increased concentration of prolactin, or they have increased sensitivity to prolactin. This can occur with a more rapid than usual decline in progesterone when dogs are spayed during diestrus. Hyperprolactinemia that occurs in response to visual stimuli of the presence of surrogate neonates results in the mammary development, lactation, maternal behavior, and other clinically apparent changes of pseudopregnancy. Uterine changes in pseudopregnancy can include the formation of placental sites and mucometra in the absence of fetuses.

1286

1287

Endometrial atrophy is usually due to loss of ovarian function secondary to hypopituitarism, and the endometrial atrophy of old age is not seen in domestic species. In the mare, diffuse endometrial atrophy occurs in anestrus and also occurs, but much less commonly, because of the ovarian inactivity of debility and chromosomal aberrations. Focal endometrial atrophy of unknown cause sometimes occurs in the mare. Atrophic endometrium is thin and flat. In the mare, the longitudinal folds are indistinct in atrophic areas, and in the cow, the caruncles are flattened. The uterus of the mare has been most studied microscopically because data from uterine biopsies are frequently used for the management of breeding. The endometrium of the uterus of the anestrous mare has cuboidal luminal and glandular epithelium, with short, straight glands.

Endometrial polyps are common lesions in older bitches and queens. They are localized increases in endometrial stroma and glands. Their cause is not known and may be an age-associated change. They are localized swellings or nodules, and some have a narrow base (Fig. 18-23). They can cause obstruction and mucometra.

Endometrial hyperplasia can be localized or generalized, is an important lesion in the ewe, bitch, and queen, and is rare in the mare. In farm animals, it is caused by prolonged hyperestrogenism. Ingested estrogenic clover such as subterranean (*Trifolium subterraneum*) and red (*Trifolium pratense*) clover is the most likely source of estrogen in the ewe. Cystic follicles, granulosa cell tumors, and estrogens from plants are causes of endometrial hyperplasia in the cow. The mycotoxin zearalenone obtained from moldy feed is a cause in the sow. In ewes, endometrial hyperplasia results in reduced fertility, dystocia, and uterine prolapse because of uterine hypotonicity. Glands of the endometrial type can develop in the cervical mucosa. Even when nonpregnant, ewes have mammary gland enlargement. Endometrial cysts, about 1 cm in diameter in the ewe, are filled with clear fluid. The cysts are both beside and beneath the caruncles. Endometrial hyperplasia is not precancerous in domestic animals, as it can be in women.

**Fig. 18-23 Endometrial polyp, cat.** The uterine horn on the left is distended by a solid cylindrical polyp that is connected to the endometrium by a narrow stalk. (Courtesy Dr. G. Foley, Pfizer Inc.)

In the bitch, and presumably the queen, cystic endometrial hyperplasia (CEH) is a common response of the uterus ([Fig. 18-19](#)). It occurs mostly in diestrus. The disease can be reproduced by estrogen priming of dogs followed by progesterone administration, but this may not be the physiologic mechanism. Bacteria are almost always present in the uterus of dogs with CEH. Increased concentration of progesterone in late estrus or early diestrus and aberrant hormonal function may alter hormonal receptor expression. This may prime the uterus so that inflammation or irritation by bacteria (or other substances, such as suture material and oil) stimulates the uterus to undergo hyperplasia and the type of change seen in early pregnancy—the so called decidual reaction.

Simple endometrial hyperplasia can be overlooked or be recognizable grossly when mild and patchy or diffuse thickening involves the endometrium. When it progresses to the stage of cystic endometrial hyperplasia, the lesion is readily recognized at necropsy. Microscopically the main component of endometrial hyperplasia is an increase in the size and number of glands with no change in the stroma except for edema. The glandular epithelium is progestational in appearance, (i.e., the cells are columnar, hypertrophic, and hyperplastic, and have clear cytoplasm) ([Fig. 18-18, B](#)). As the glands become cystic, the pressure of retained secretion is increased, and the epithelium of the glands becomes flattened.

1287

1288

Bitches and queens are likely to progress to pyometra. In all species, the cystic lesions are probably irreversible.

Mucometra and hydrometra are the accumulation of mucus and clear fluid, respectively, in the uterine lumen ([Fig. 18-24, A and B](#)). The cause is congenital or acquired obstruction of the outflow of mucus

## Pathologic Basis of Veterinary Disease, 4th Edition

initially produced in normal amounts. However, mucometra can be due to the production of excessive amounts of mucus in cases of hyperestrogenism. Mucometra occurs in pseudopregnancy, where it resolves spontaneously. Mucometra or hydrometra from obstructive lesions will contribute to infertility.

Adenomyosis is occasionally encountered in domestic animals, notably the bitch, queen, and cow. Adenomyosis is the presence of nests of endometrium within the myometrium, and the effect generally is negligible in domestic animals, which do not menstruate. Sometimes the uterus undergoes diffuse symmetric or focal asymmetric enlargement (Fig. 18-25). Microscopically, endometrial glands or stroma or both have extended from the basal endometrium beyond the junction between endometrium and myometrium. Endometriosis is a lesion of importance only in primates, in which the endometrium goes through the proliferative, secretory, and menses (shedding) phases. Endometriosis is the presence of endometrial glands or stroma in locations outside the uterus, such as the ovary, the mesometrium, the peritoneum, and peritoneal surgical scars. The phases of the menstrual cycle result in a buildup of the products of menses in the extrauterine sites that cause inflammation, fibrosis, and pain.

**Fig. 18-24 Mucometra and hydrometra, uterus. A, Mucometra, mare.** Note the accumulation of mucus within the opened body of the distended uterus. **B, Hydrometra, goat.** The uterine horns and body are filled with clear watery fluid. Ladds, James Cook University of North Queensland.)

18.2.1.4.3

### Neoplasms

Uterine neoplasms are not common in domestic animals. The primary ones that do occur with any significant frequency are carcinoma in the cow and leiomyoma in the bitch. Lymphosarcoma in the cow is the most often encountered metastatic neoplasm.

Leiomyomas in the bitch are often multiple neoplasms, not only in the uterus, but also in the cervix and vagina (Fig. 18-26, A and B). Estrogens likely have a role in provoking and maintaining these neoplasms

1288

1289

## Pathologic Basis of Veterinary Disease, 4th Edition

---

in the bitch. In other species, however, these neoplasms are rare, tend to be single, and have no unusual hormonal background. The neoplasms are well demarcated but not encapsulated, are usually spherical, and vary greatly in size. Depending on size, they can be confined within the wall of the vagina, cervix, or uterus or can protrude into the lumen or project to the serosal surface or into the pelvic canal. Some luminal neoplasms, especially those in the vagina, are pedunculated, making them liable to trauma or torsion. They are usually firm, pink or white, and occasionally calcified or edematous. The color is related to the amount of fibrous tissue present along with the whorled smooth muscle cells; in the grossly white neoplasms, fibrous tissue is the predominant component.

**Fig. 18-25 Adenomyosis, uterine body, bitch.** Formalin fixed specimen. The myometrium (*outer portion*) is infiltrated and expanded by multiple cysts of endometrial stroma and glands. Many of these glands are filled with pus, and the endometrium is expanded as a result of inflammation secondary to bacterial infection. (Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph.)

**Fig. 18-26 Leiomyoma, uterus, bitch.** **A**, Note the well-circumscribed, firm mass in the left uterine horn. **B**, The cut section of the leiomyoma reveals gelatinous content with bands of smooth muscle and connective tissue. This mass is within and arising from the myometrium. (**A** and **B**, Courtesy Dr. D. D. Harrington, College of Veterinary Medicine, Purdue University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Carcinoma of the endometrium is rare in domestic animals as a clinical problem, but it is well known as a lesion of the bovine uterus found at the time of meat inspection. In the cow, the early carcinoma is found most often in the depths of the endometrial glands of the horns and less often in the body of the uterus. As it increases in size, the neoplasm thickens the uterine wall without any distortion of the overlying endometrium. A scirrhous response, the deposition of large amounts of fibrous tissue, is a characteristic lesion and makes the neoplasm firm and causes localized constriction bands on the external surface. The neoplasms can be small and annular or involve a large area of the uterine wall. Microscopically the neoplasm is readily distinguished from normal endometrium by the increased size, pleomorphism, and disarray of the glandular epithelial cells and the accompanying scirrhous reaction. Metastases occur to the regional lymph nodes (iliosacral) and lungs, and they seed the serosal surfaces of the abdomen.

Lymphosarcoma in the cow in the enzootic form is caused by the bovine leukemia retrovirus and commonly affects a tetrad of organs, namely the heart, abomasum, lymph nodes, and uterus. In the uterus, as in other locations, infiltration of neoplastic cells can be focal, multifocal, or multifocally coalescing and up to 3 cm thick (Fig. 18-27). Affected areas are light yellow, slightly friable, and sometimes centrally necrotic and thicken or replace any or all layers of the uterine wall. It is not uncommon for the cervix, vagina, and uterus to have lesions. In such cows, the vaginal lesions are

## Pathologic Basis of Veterinary Disease, 4th Edition

multiple, small, often hemorrhagic, but nonulcerated nodules. An extensively involved uterus can support pregnancy even to an advanced stage.

**Fig. 18-27 Lymphoma (lymphosarcoma), uterus, cross section, cow.** The mucosa, lamina propria, and myometrium are all heavily infiltrated by neoplastic lymphocytes. The dark-red to brown regions are areas of necrosis and hemorrhage. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

1289

### 18.2.1.5 PLACENTA AND FETUS

1290

#### 18.2.1.5.1 Failure of Pregnancy

Maintenance of pregnancy is one of those miraculous events that often defy logic, and there is probably more that is not known than is known about pregnancy and embryonic and fetal development. The fetus is allogenic and therefore foreign to the mother. Yet it survives, even though both fetus and mother could mount an immune response to each other. Tolerance or suppression of the maternal immune system is

## Pathologic Basis of Veterinary Disease, 4th Edition

---

required, but the mechanisms are incompletely understood, and there is little agreement about how this actually occurs. Theories, particularly in those species in which the fetal tissues invade the maternal system, involve the role of several potential processes, including an active role of systems like the Fas/Fas ligand system in which active immune cells undergo apoptosis when in contact with cells (trophoblasts) expressing the Fas ligand. Another system involving the suppression of maternal immunity in the uterus is indoleamine 2,3 dioxygenase (IDO), which inhibits tryptophan, an amino acid necessary in the growth and development of T lymphocytes. Combined with the relative lack of MHC expression on trophoblasts, alteration of T helper lymphocyte balance and suppressor lymphocytes combine to partially explain the paradox that is pregnancy.

Immunologic considerations are only a part of the pregnancy equation. There are hormonal influences, especially maintenance of progesterone concentration. Stressors and systemic cytokines, such as prostaglandin, can cause luteolysis of the corpus luteum (where appropriate) and terminate pregnancy.

It is generally believed that fetuses initiate their own parturition. In conditions of fetal stress—such as maternal or fetal illness, hyperthermia, and hypoxia—they initiate the cascade of events that results in parturition. Initiation of birth by this process should result in a fresh (nonautolyzed) fetus, whereas rapid fetal death is believed to result in loss of pregnancy by other mechanisms, and the fetus, having spent additional time at body temperature, will be autolyzed.

The conceptus is the product of conception, and it is composed of the embryo, that part of the conceptus that gives rise to the adult, and the membranes. Embryos become fetuses at the time they develop features that allow their species and sex to be determined phenotypically. This occurs at about 35 to 45 days of age in large animals. Movement of the fetus occurs at this time. Loss of pregnancy is divided into stages based on the fetus's development and potential viability. Early embryonic mortality occurs at the embryonic stage, and abortion occurs during fetal development but when the fetus is not independently viable. Stillbirth occurs when the fetus is potentially viable. Fetal death later in development will lead to abortion, mummification, or maceration (Table 18-3). Mummified fetuses may be retained indefinitely if there is only one fetus. *Maceration* means to become soft and liquefy and requires bacterial infection of the fetus.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 18-3 Failure of Pregnancy

GUIDE TO FETAL AUTOLYSIS*	
Time Since Death	Change
12 hr	Cornea cloudy, amnionic fluid blood tinged
24 hr	Fluid in body cavities
36 hr	Gelatinous fluid in subcutis
72 hr	Eyes dehydrated
144 hr	Carcass dehydrated, no abomasal contents
COMMON CAUSES OF FETAL MUMMIFICATION	
Horse	Twinning

\* Data from Dillman RC, Dennis SM: Am J Vet Res 37: 403–407, 1976.

Embryonic and fetal death deprive the fetomaternal unit of whatever contribution the conceptus makes to the continuation of pregnancy. Parturition and (presumably) abortion in most animal species is initiated by the fetal adrenal gland. A signal, perhaps a stressful event, causes the fetal pituitary to secrete ACTH that in turn results in glucocorticoid production by the adrenal gland. Corticosteroids increase the synthesis of estrogens in the placenta, which in turn causes the synthesis and release of  $\text{PGF}_{2\alpha}$  from the endometrium and myometrium. This causes luteolysis and a decreased progesterone production. In large animals, the loss of very small embryos does not influence the time of return to estrus. If embryonic loss occurs later, the interval to the next estrus will be somewhat increased because the corpus luteum will have been programmed for prolongation of its life. The importance of the fetal component and the necessity of the presence of a corpus luteum for the entire pregnancy vary with species. For instance, the corpus luteum of the sow is necessary throughout pregnancy because progesterone production by the placenta is small, but in the mare, the corpus luteum regresses halfway through pregnancy and placental progesterone maintains pregnancy. Regardless of the source of hormones responsible for maintaining pregnancy in large animals, embryonic or fetal death permits the release of  $\text{PGF}_{2\alpha}$  and expulsion of the embryo or fetus. The exact outcome is unpredictable and is influenced, among other things, by species, stage of gestation, and number of fetuses. In the bitch and queen, the life span of the corpus luteum is not very different between pregnant and nonpregnant animals. When embryonic or fetal death occurs in domestic carnivores, the demise of the corpus luteum is definite and dead products of conception may be retained until approximately the normal time of parturition. Fetal autolysis is therefore common.

1290

1291

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Mummification is one of the possible outcomes of fetal death. Rather than being expelled soon after death, the fetus is retained and progressively dehydrates to become a firm, dry mass, which is discolored by degraded hemoglobin to brown or black, and consists of leathery skin enclosing the harder parts of the fetus (Fig. 18-28). The cause of death can be infectious or noninfectious, but requisites for mummification are organisms that promote lysis of dead tissue be absent and that the cervix be closed to prevent the entry of putrefactive organisms. The situations in which mummification most commonly occurs are listed in Table 18-3. In twin pregnancy in the mare, the mummified fetus and the longer surviving fetus are aborted together before term. In parvovirus infection in the sow, mummified fetuses are retained and born at term along with live fetuses. In any species with a single fetus pregnancy, the mummified fetus can be expelled at any time or retained indefinitely.

**Fig. 18-28 Failure of pregnancy, mummified fetus, pig.** This fetus died in utero, and the fluids were resorbed. Dehydration of a fetus in utero usually takes longer than 1 week to occur. (Courtesy Ontario Veterinary College, University of Guelph.)

**Fig. 18-29 Failure of pregnancy, macerated fetus, lamb.** Fetal bones, hair, and brown pasty material fill the uterus. The ewe was infertile. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Maceration of a dead fetus requires the presence of bacterial organisms in the uterus. These bacteria could be the ones that caused the fetal death in the first place or could be putrefactive organisms that entered the uterus via the cervix after the death of the fetus. In addition to disintegration of the fetus (Fig. 18-29), the uterus has lesions also. Endometritis or pyometra is present; the type of lesion depends on whether the cervix is open or closed. Endometritis and pyometra tend to become severe and chronic, with voluminous pus in the case of pyometra. Emphysema occurs with the invasion of the fetus by clostridial organisms. Maternal toxemia and death are likely. Fetal bones resist maceration, and if the uterus eventually regains some muscular tone, the bones can cause perforation.

The general diagnostic rate for determination of the cause of failure of pregnancy is low and with few exceptions is less than 40%, although success is usually much greater in outbreaks (Table 18-4). Many of the recognized causes are infectious because infections are usually easy to diagnose (Table 18-3). This has led to the general approach of determining if the loss of pregnancy is infectious or not.

### 18.2.1.5.1.1

#### Examination of fetus and membranes

Early embryonic mortality or death of the embryo or loss of pregnancy at this early stage of gestation is thought to result in dissolution, but it is also valid that the conceptus is so small that it is not found. The absence of material for diagnostic purposes often hampers the identification of the cause. There are recognized infectious causes of infertility, and the infection often occurs at or near the time of coitus or conception. Agents such as *Campylobacter*, *Tritrichomonas*, and *Ureaplasma* and nonspecific endometrial infections are among the common examples.

Caprine	<i>Brucella melitensis</i> Iodine deficiency
Porcine	Leptospirosis
These are not the most common in all areas. Common causes are listed in <a href="#">Table 18-4</a> .	

It appears that chromosomal abnormalities account for the majority of noninfectious causes. Regardless of which species is involved, investigation of abortion or stillbirth requires a keen sense of what can be achieved. Depending on the situation, the investigation may have an economic impact, a zoonotic impact, or it may appeal to your scientific curiosity. Maternal, fetal, and placental factors should be considered. There are causes that are common across all species that are listed in [Table 18-3](#) and causes that are species specific or are regionally important causes of abortion that are listed in [Table 18-5](#).

Examination of the fetus and membranes, and sampling of tissue primarily answers the question: Are there any fetal or placental abnormalities to explain the abortion or stillbirth? Some of the lack of success in determining the cause is the failure to submit the appropriate specimens. Where feasible, send the whole fetus and membranes to the laboratory. When this is not feasible, success in ruling out

## Pathologic Basis of Veterinary Disease, 4th Edition

---

fetal factors depends on submission of the correct specimens, and this in part depends on knowing what specimens to send. Each diagnostic laboratory has a recommended list of samples that are suggested to maximize diagnostic success in their particular locale.

Each species and breed of animal has an expected rate of development and an average size at birth. Variance of this normal development indicates an abnormality that needs to be explained. Fetal and placenta weight, fetal size, including crown-rump length, and degree of development for gestation length are basic parameters that may indicate increased or inadequate maternal nutrition, concurrent disease, or placental sufficiency.

The degree of fetal autolysis and evidence of fetal distress will provide an indication of the fetal state just before the loss. When distressed and hypoxic, a fetus will gasp and aspirate amniotic contents, and meconium will be released into the amniotic fluid. Meconium staining of the skin can be seen grossly (Fig. 18-30). Keratin squames and meconium from the amniotic fluid will be found in the lungs when histologic assessment is done. A fetus that is caught in the birth canal for a sufficient period of time will develop localized swellings, such as a swollen tongue and face (Fig. 18-30). Fetal autolysis was studied in sheep and gives an approximation of the time of fetal death before expulsion. It is generally believed that an autolyzed fetus dies too quickly for it to initiate its own parturition, as would occur with fetal sepsis or viremia. A fresh fetus initiates its own parturition.

1292

1293

**Fig. 18-30 Dystocia, lamb.** This large lamb died during parturition. It was trapped in the birth canal by the shoulders and right foreleg, which has flexed (folded back). The lamb became hypoxic and defecated meconium, visible as a yellow deposit on the skin of the body caudal to the shoulder. The head and left foreleg became swollen and the skin dry. The skin of the rest of the body is moist from amniotic fluid (and meconium), indicating that this portion of the body was in the vagina and uterus. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

**Fig. 18-31 Iodine deficiency, goiter, goat fetus.** This fetus has bilaterally extremely enlarged thyroid glands, alopecia, and myxedema evident subcutaneously over the thorax and abdomen, the classic lesions of severe hypothyroidism. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Fetal mummification occurs periodically in animals and has a common cause for each species, which is listed in [Table 18-3](#).

The fetus is similar to an adult in the general response to diseases ([Fig. 18-31](#)), particularly near parturition, but many of the responses will be rudimentary, depending on the stage of gestation. To our knowledge, the fetus is in a sterile environment, and has no flora or fauna. Exposure to environmental or pathogenic agents occurs from contact with the external environment or with maternal infection. Many of the pathogens have an affinity for the reproductive tract and may infect and/or initiate failure of pregnancy in many species. Agents common to all species are listed in [Table 18-3](#). Some of them are discussed next.

### 18.2.1.5.1.2

#### Species-specific failure of pregnancy

Each species has its known causes and profile of lesions and conditions that result in the failure of the pregnancy. [Table 18-4](#) lists the likely diagnostic success and the types of diseases and conditions to expect. Some of the conditions are specifically discussed in the following sections. Horses are unique in having a large number of noninfectious causes of abortion ([Box 18-5](#)), related in many instances to the apparent lack of placental reserve and microcotyledonary placentation. Examination of the placenta for lesions requires knowledge of normal anatomy, and there are many features and structures that are normal but have the appearance of being a lesion ([Box 18-6](#)). It is important to assess the equine placenta for anything that reduces placental area, such as avillous areas, involvement of the cervical star ([Fig. 18-35](#)), examination of the umbilical cord for excessive length (normal is 36 to 84 cm) and torsion ([Fig. 18-40](#)), and lesions of the amnion.

### Box 18-7 Lesions of Chronic Placentitis in Ruminants

Placental edema

Intercotyledonary opacity

Intercotyledonary fibrosis

Cupping of cotyledon

Cotyledonary necrosis

Exudates

The placentation of ruminants is cotyledonary, and as such there is a large potential space between the placentomes for exudates and agents to accumulate. As such, chronic placentitis centered on the pericotyledonary area and the intercotyledonary portion of the chorion is more common (Box 18-7). Porcine, feline, and canine placentas rarely have lesions.

18.2.1.5.2

### Infectious Diseases

The most common diseases of the fetus and placenta across the species are infectious, except perhaps in the mare. Bacterial, viral, and protozoal agents and combinations all occur. With each agent, however, the significance of the infection should be determined by association with lesions or the known pathogenetic mechanisms.

18.2.1.5.2.1

### Bacterial diseases

Bacterial species causing inflammation of the placenta and fetus are numerous. Almost any organism that causes septicemia can infect the pregnant uterus, but the following discussion concerns those organisms that target the placenta or fetus, or both. The route of invasion of the uterus and fetus for many animal species and many bacteria (such as salmonellae and brucellae) is hematogenous, after the organisms have entered the dam either through the digestive or genital tract. For some diseases, the method of spread is venereal (*Campylobacter* sp., *Ureaplasma* sp.). In the mare, most placental pathogens enter the pregnant uterus through the cervix.

Brucellosis is now a rare or sporadic disease of all species, but there are many similarities in the lesions and pathogenesis among the domesticated species. *Brucella abortus* infection in cattle is now eradicated from many states and provinces. It is, however, a much studied and classic cause of abortion. The placental lesions are stereotypical and are shared by other agents. *Brucella abortus* is ingested with feed contaminated by an infected aborted fetus or placenta. The initial lesion is a persistent nasopharyngeal lymphadenitis. Bacteria are released into the blood in waves, causing

## Pathologic Basis of Veterinary Disease, 4th Edition

bacteremia and bacteria to colonize the spleen, lymph nodes, mammary glands, testes, male accessory genital glands, and joint capsules, bursae, and tendon sheaths. *Brucella* organisms are removed from most organs, but a small nidus of infection usually persists in some organ. The pregnant uterus is particularly susceptible to infection, and the uterine disease process becomes chronic, eventually resolving after abortion or parturition.

Gross lesions in the placenta are edema of the intercotyledonary chorioallantois that is opaque with a leathery texture, light brown exudate on the chorionic surface, and various extents of necrosis of the cotyledons. A placenta with such lesions is grossly indistinguishable from the placenta of cases of mycotic abortion (Fig. 18-32) or the rare case of campylobacteriosis with a late-term abortion. The fetal lesions are nonspecific and consist of edema and fluid accumulation in body cavities; often more specific lesions include bronchopneumonia and pleuritis. Microscopic lesions include inflammation with edema and infiltration of mononuclear cells and a few neutrophils of both the intercotyledonary chorion and the chorionic villi. A striking feature is the presence of numerous gram-negative coccobacilli within trophoblasts, many of which are desquamated and form the considerable debris between maternal and fetal tissues.

In ruminants, *Brucella abortus* moves from the maternal circulation into the hemophagous organ where erythrophagocytosis occurs at the tips of the maternal septa within the placentome. Organisms are

1294

then phagocytosed by the erythrophagocytic trophoblasts at the nearby base of the chorionic villi.

1295

Replication occurs in adjacent periplacentomal chorioallantoic trophoblasts. Replication is followed by trophoblast necrosis and chorioallantoic ulceration. Organisms enter the uterine lumen and chorionic villi to finally disseminate hematogenously to fetal viscera. *Brucella abortus* appears to be taken up by endocytosis through erythrophagocytic trophoblasts and replicates in the rough endoplasmic reticulum of the periplacentomal and interplacentomal trophoblasts, a unique mechanism of intracellular parasitism. Vasculitis occurs in both maternal and fetal tissues and the lesion could be a response to endotoxin released from the *Brucella* organisms. Most fetuses have pneumonia that ranges from minimal to severe. Microscopically the pneumonia is either a chronic bronchopneumonia with an exudate of numerous mononuclear cells and some neutrophils or a fibrinous pneumonia. Microscopic granulomas that include multinucleate giant cells occur in various organs, such as the lung, liver, spleen, and lymph nodes.

**Fig. 18-32 Mycotic intercotyledonary placentitis, cow.** Marked edema, fibrosis, and thickening of the intercotyledonary placenta has caused it to be opaque. The cotyledon on the right is necrotic. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Brucella canis* is acquired by the dog either through ingestion or venereally. Both sexes have lymphadenitis, especially of the nodes of the head and neck, and bacteremia. Epididymitis and testicular degeneration are the lesions in male dogs, and females have placentitis and fetal endocarditis, pneumonia, and hepatitis. Microscopically, trophoblasts are packed with *Brucella* organisms. Other fetal lesions include renal hemorrhage, subacute inflammation of the pelvic connective tissue, and lymphadenitis.

*Brucella ovis* in sheep is probably transmitted venereally from a ram with epididymitis shedding large numbers of organisms in the semen. Gross placental lesions are essentially similar to those produced by *Brucella abortus* in cattle. Fetal lesions at necropsy are nonspecific (e.g., edema and fluid accumulation in the body cavities). Calcified plaques on the hooves have been noted but are not specific for this agent. Microscopically, as with *Brucella* sp. infections in other species, large numbers of coccobacilli are found in trophoblasts and are free in the chorionic mesenchyme. Vasculitis involves the larger chorionic vessels. Lesions in the fetus are pneumonia, lymphadenitis, interstitial nephritis, and pericholangitis. In younger fetuses, infiltrates of monocytes and macrophages are present, whereas older fetuses have well-formed nodules of lymphocytes and plasma cells. *Brucella melitensis* infection in sheep and goats occurs mainly in Mediterranean countries. The infection has a septicemic phase, but inflammation is localized to the mammary gland and pregnant uterus. Goats have more severe febrile disease and more severe mastitis than do sheep.

*Brucella suis* causes a disease in pigs that differs in several respects from brucellosis in ruminants. The lesions are more widespread and have a predilection for bones and joints. Necrosis with caseation occurs in many lesions. Pregnancy is not a prerequisite for endometritis in porcine brucellosis. Miliary granulomas in the endometrium are mixed with multiple hyperplastic lymphoid nodules. Endometrial glands become distended with mucus and leukocytes, and the surface epithelium is partly desquamated and focally has squamous metaplasia. Between placentas of the pregnant uterus, the lumen has a mucopurulent exudate in which intracellular and free organisms are plentiful. The chorioallantoic membranes have nonspecific lesions of edema and congestion.

Campylobacteriosis is a sporadic disease in most species, but is particularly seen in ruminants. *Campylobacter fetus* var. *venerealis* can be a long-term inhabitant of the preputial cavity of bulls. It is transmitted venereally and can survive for some time on the vaginal mucosa, but the cow must become pregnant for it to establish itself in the uterus. Early embryonic death is the most likely manifestation of campylobacteriosis and often the only clinical abnormalities are irregular estrus cycles or the return to estrus of an animal thought to be pregnant. Much less frequently abortion occurs at a later stage of pregnancy. Cows become resistant to subsequent infections by the bacterium. Gross and microscopic lesions in placentas are similar to those described in brucellosis (edema of the intercotyledonary chorioallantois and necrosis of cotyledons with microscopic inflammation of both) but are less severe and with fewer organisms in the desquamated trophoblasts. Fetal lesions are nonspecific.

*Campylobacter fetus* ssp. *fetus* and *Campylobacter jejuni* are primarily intestinal inhabitants and cause similar lesions in sheep. The organisms are transmitted by ingestion, and abortions occur in outbreaks. Infection of the pregnant uterus results in late-term abortion or the birth of live, but sick lambs. Immunity is gained after the first infection. The placentitis is characterized by an edematous intercotyledonary chorioallantois and friable, yellow cotyledons. Grossly, about 25% of the fetuses have multiple yellow areas of hepatic necrosis from 10 to 20 mm in diameter with red, depressed centers. Microscopically the chorioallantois is infiltrated by a mixture of cells, mostly neutrophils, but

## Pathologic Basis of Veterinary Disease, 4th Edition

many cells are necrotic and cannot be identified. Inflammation is especially severe in the chorionic villi. *Campylobacter* organisms are abundant among the inflammatory cells. A diagnostically useful lesion in campylobacterial infection is the presence of large, dense emboli of bacteria in the capillaries of the chorionic villi. The fetal lesions are those of a severe multifocal necrotizing hepatitis with abundant organisms. *Flexispira rappini* causes similar lesions in the ovine placenta and fetus, but infections are sporadic.

1295

1296

**Fig. 18-33 Intercotyledonary placentitis (*Coxiella burnetii*), goat.**  
Note the opacity of the intercotyledonary placenta caused by thickening from inflammation and fibrosis. The cotyledons have variable areas of gray discoloration, indicating necrosis and inflammatory exudates. The gross appearance of the lesions of placentitis tends to be similar, regardless of the etiologic agent identified by microbiological examination. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

*Coxiella burnetii*, the cause of Q fever in human beings, is responsible for abortion or the birth of dead or weak lambs or kids. Abortion occurs in newly exposed animals and repeat infection with abortion is possible. Infection of goats is more common. Transmission of the organism is either by ingestion or by inhalation. The organism is shed in vaginal discharges at parturition and in the milk. This organism is readily transmitted to human beings by the same ways. In affected goats, the intercotyledonary chorioallantois is thick, leathery, yellow, and covered with surface exudate (Fig. 18-33). Gross fetal lesions are nonspecific. Microscopically the placental lesions of acute inflammatory infiltration are most severe in the intercotyledonary areas. Hypertrophic trophoblasts are filled with *Coxiella* organisms. Fetal lesions, if present, consist of peribronchiolar, renal medullary, and hepatic portal lymphoid accumulations.

Enzootic abortion of ewes is caused by *Chlamydophila abortus* and is one of the most common abortifacient agents in sheep. It occurs in outbreaks when newly introduced into flocks, or as an

## Pathologic Basis of Veterinary Disease, 4th Edition

---

enzootic condition of ewe lambs. It occurs in all sheep-producing countries, producing late-term abortion in ewes. Transmission is generally oral and ewes seem to be immune to reinfection after the first abortion, but they may remain as carriers. Ewes infected before 5 or 6 weeks of gestation abort in late gestation, but ewes infected after 5 or 6 weeks of gestation abort the subsequent pregnancy. The placenta in affected ewes grossly is similar to the placenta in *Coxiella* infection and in ovine brucellosis. Microscopically the chorioallantois is infiltrated by neutrophils. Cotyledons have more severe inflammation than the intercotyledonary areas. The organisms distend the trophoblasts but are difficult to visualize without special stains, such as modified Ziehl-Neelsen or Gimenez stains. In the fetus, subacute inflammatory foci may be present in several organs, especially the liver, lungs, and muscle.

Epizootic bovine abortion, also known as foothills abortion, occurs in California and adjacent states. The causative agent is unknown, with *Chlamydophila*, *Borrelia*, a spirochete, and viruses having been suggested and excluded. Abortion or the birth of weak calves occurs only in cows newly introduced into the territory of the tick *Ornithodoros coriaceus*. The fetal disease is chronic with notable microscopic lesions 50 days after tick exposure of the dam. The lesions are of sufficient specificity for a diagnosis in fetuses whose gestational age is greater than 100 days. Gross lesions include petechial hemorrhages of the conjunctiva and oral cavity, an enlarged nodular liver and ascites (presumably from heart failure secondary to myocarditis), and enlarged lymph nodes and spleen. Lymphoid follicles are hyperplastic and have large numbers of histiocytes. The thymus is atrophic because of the loss of cortical lymphocytes. The thymic parenchyma and interstitium are infiltrated by histiocytes. Foci of acute necrosis are present in several organs, especially the lymph nodes and spleen. These foci frequently develop into pyogranulomas. Vasculitis, acute or subacute, occurs in several organs. Deposits of IgG and IgM are present in the vascular lesions.

Leptospirosis is another possible cause of abortion. Results of serologic studies indicate that a large percentage of cattle and pigs are infected, but most animals do not have clinical signs. Several different serovars are associated with abortion, especially *Leptospira interrogans* serovar *hardjo* in cattle and serovar *pomona* in pigs. In adult animals, the organisms localize in the kidneys after the septicemic phase. Pregnant sows or cows abort weeks after the septicemic phase, usually in the last trimester. Placental lesions are usually limited to edema. Fetal lesions often are mild and obscured by autolysis. Some dead fetuses expelled near term without extensive autolysis have gross lesions of ascites and fibrinous peritonitis. Microscopic lesions include subacute interstitial nephritis and subacute necrotizing hepatitis. With or without morphologic changes in the fetal kidneys, leptospiral organisms may be demonstrated in peritoneal or pleural cavity fluid by dark field microscopy and in renal tubular lumens by silver stains or by immunohistochemical techniques. Measurement of the leptospiral antibody in fetal fluids (serum, cavity fluids) is a major method for diagnosis.

1296

Listeriosis caused by *Listeria monocytogenes* is a cause of sporadic abortions in cattle, sheep, and goats and of outbreaks of abortion in sheep. Although both nervous disease and reproductive disease occur in the same flock or herd, this is rare. Listerial abortions occur in the last trimester of pregnancy. Some aborting dams are septicemic and have endometritis. The placental lesions include severe diffuse necrotizing and suppurative inflammation of both the cotyledons and the intercotyledonary areas. Fetal lesions are an enlarged liver with numerous 1-mm yellow foci. These yellow foci are areas of acute multifocal necrotizing hepatitis in which the necrotic cells are also filled with gram-positive *Listeria* organisms. Other fetal organs have similar microscopic lesions. Microscopically, severe inflammation involves the mesenchyme of the villi and the upper intercotyledonary chorion, with some of the cells degenerated beyond recognition. Trophoblasts, especially in the areas between the villi, are filled with gram-positive listerial bacilli.

1297

Fig. 18-34 **Amnionitis, *Ureaplasma diversum* infection, cow.** The amnion has large, opaque, red and white areas of granulation tissue and fibrous tissue, respectively. Amnionitis without placentitis in cattle is a good indicator of *Ureaplasma* sp. infection. (Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph.)

Fig. 18-35 **Bacterial placentitis, cervical star, mare.** The chorion at the cervical star is thickened by edema, and there is fibrin, necrotic debris, and suppurative exudate on the surface. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

Organisms that cause bacteremia in adult animals are capable of causing lesions in the placenta and fetus. Thus in cattle, bacteria such as *Salmonella*, *Mannheimia*, and *Pasteurella* spp. and *Histophilus somni* are potential causes of placentitis, fetal inflammatory lesions, and abortion. In pigs, various *Streptococcus* spp. can cause similar lesions. *Ureaplasma diversum* can cause abortion in cattle. The placental lesions include focal or diffuse reddening of the amnion and chorioallantois, accompanied

## Pathologic Basis of Veterinary Disease, 4th Edition

---

by thickening and yellow discoloration of the amnion (Fig. 18-34). Fibrosis, edema, inflammation, and necrosis of the amnion occur together with focal inflammation and necrosis of the cotyledons and the intercotyledonary chorioallantois.

Because ascending infection is the most common route of infection of the placenta in the mare (Fig. 18-35), various bacterial organisms are involved. Hemolytic streptococci (especially *Streptococcus zooepidemicus*) are the most frequently recovered from fetal organs, placentas, and uterine discharges. Other commonly encountered organisms are *Escherichia coli* and *Pseudomonas*, *Klebsiella*, and *Staphylococcus* spp. Although some infections are hematogenous, the ascending route of infection, through the cervix, is the rule. Inflammation of the chorioallantois is most severe opposite the cervix, and the area involved usually extends further ventrally than dorsally because of gravitational spread. Affected parts of the placenta are edematous and brown and covered by small amounts of fibrinonecrotic exudate. Gross fetal lesions are enlarged liver and increased abdominal and thoracic fluid. Microscopically the lesions are severe subacute inflammation of the stroma of the chorionic microcotyledons and desquamation of chorionic epithelium. Microscopic fetal lesions are rare, despite the ease with which bacteria can be recovered from many fetal organs. The prelude to abortion is either fetal death from septicemia or placental insufficiency.

18.2.1.5.2.2

### Fungal diseases

*Aspergillus* and the zygomycetes (*Absidia*, *Mortierella*, *Rhizopus*, *Mucor*) cause sporadic abortions in cows and mares. In cows, the organisms spread to the placenta hematogenously, as indicated by the fact that the placentomes are involved first and there is random involvement of the placentomes. In the mare, as with bacterial placentitis, the fungi enter through the cervix because the lesions in the chorioallantois are most severe in or even confined to the cervical area. In the affected bovine placenta, the cotyledons become enlarged, brown, and friable and the intercotyledonary chorioallantois becomes leathery and covered with a brown exudate (Fig. 18-32 and Fig. 18-36, A and B). Thus the gross appearance of the placenta is similar to the classic descriptions of the placenta in bovine brucellosis. Affected areas of the equine chorioallantois are brown, initially thickened, and later shrunken and friable. In both bovine and equine species, the amnion has thick, white or yellow, leathery areas. Small, white, raised plaques are present on the skin of the bovine fetus and sometimes on the equine fetus. Microscopically the lesions include inflammatory cell infiltration of amniotic and chorioallantoic mesenchyme and desquamation of trophoblasts. In the bovine species, the lesions of vasculitis and fungal vascular invasion involve the larger vessels at the base of the cotyledons. Lesions in the fetus are confined to the skin and include subacute dermatitis and hyperkeratosis. Fungal hyphae, septate in the case of *Aspergillus* and nonseptate in the case of the mucorales and hyphomycetes, are abundant in the lesions of the placenta and the skin of the fetus. Fungi can be recovered from the fetal stomach, presumably from swallowed amniotic fluid.

1297

1298

Fig. 18-36 **Mycotic endometritis, postpartum uterus, cow.** **A**, The endometrial surface of the middle and lower portion of this uterus is irregularly thickened and corrugated. Caruncles are small or missing. **B**, The placenta is necrotic, and the numerous fungal hyphae (*black*) are irregular in diameter, do not have regular septation, and branch at odd angles, all features typical of *Mucor* spp. Gomori's methenamine silver stain. 18.2.1.5.2.3

### Viral diseases

Herpesviruses are well established as causes of outbreaks of abortion in cows, mares, and sows and are described in goats and dogs. Generally, the gross lesions in affected fetuses are multiple randomly distributed pale gray to white foci in affected organs characteristic of acute necrosis (Fig. 18-37, A). Lymphoid necrosis occurs in the spleen, thymus, and lymph nodes, whereas multiple small foci of necrosis, mild acute inflammation, and intranuclear inclusion bodies occur in parenchymal cells in a wide range of organs, especially the liver, lungs, and adrenal glands. Often the fetal liver is enlarged, and the necrotic foci are large enough to be visible as 1- to 2-mm white areas (Fig. 18-37, B). Pulmonary lesions usually include hyperplasia, focal necrosis, and desquamation of bronchiolar epithelium. Fibrinous bronchiolitis, grossly visible, is present in some fetuses, especially equine. The placenta can be edematous, but only in the sow are inflammation and inclusion bodies readily observed in the chorion.

1298

1299

**Fig. 18-37 Equine herpesvirus 1 infection, aborted equine fetus. A,** The changes typical of herpesviral abortion include solid rubbery lungs, multiple foci of necrosis in the liver, and splenomegaly. **B,** Randomly distributed multiple 1-mm white foci in the liver are characteristic of necrosis caused by herpesviral infection. This case is more florid than most. (**A**, Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph. **B**, Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Equine herpesvirus 1 (EHV-1) could be the most economically significant abortigenic animal herpesvirus. Viral infection of maternal uterine endothelial cells has a major role in the pathogenesis

## Pathologic Basis of Veterinary Disease, 4th Edition

of abortion. Damage to these endothelial cells results in thromboses accompanied by perivascular infiltration of lymphocytes, neutrophils, and monocytes and perivascular edema and subsequent infarction of the endometrium. The fluid that escapes through the damaged endometrium causes separation of the maternal and fetal layers of the placenta, and this separation could allow virus from maternal leukocytes and lysed endothelial cells to enter the fetus. Fetal endothelial cells and the cells of a wide range of organs are targets for the virus. The classic lesions are focal hepatic necrosis, pneumonia with fibrin casts in the trachea, and prominent lymphoid follicles in the spleen.

BHV-1 is a sporadic cause of bovine abortion. In addition, infectious bovine rhinotracheitis virus produces an acute necrotizing endometritis in the uterine body or caudal parts of the uterine horns of the cow, particularly in the postpartum period. Microscopically the lesions range from mild focal lymphocytic endometritis to severe diffuse necrotizing metritis.

Pestiviruses in cattle (bovine viral diarrhea [BVD] virus), sheep (border disease virus), and pigs (classical swine fever virus) can cause fetal death or malformation, depending on viral strain, fetal age, and stage of development of the fetal immune system. Placental and fetal lesions are either absent or are restricted to microscopic lymphocytic infiltrates in the heart and brain. Fetal malformations caused by these are discussed elsewhere.

**Fig. 18-38 Stillbirth, mummification, embryonic death and infertility (SMEDI), abortion, pig fetus.** Viruses such as porcine parvovirus and porcine enteroviruses induce SMEDI. These viruses affect the fetuses to differing degrees and at different stages of gestation. Those fetuses that die early in gestation are usually mummified (*bottom fetus*) or resorbed. (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Porcine parvovirus is an important cause of embryonic and fetal loss and causes death and mummification of a proportion of affected litters (SMEDI) (Fig. 18-38). Pig fetuses infected before immunocompetence have widespread necrotizing lesions, together with inflammation and inclusion bodies, especially in the liver, lungs, kidneys, and cerebellum. Damage to the fetal circulatory system results in edema, hemorrhage, and the accumulation of serosanguinous fluid in body cavities.

Arteriviruses are important in causing failure of pregnancy in animals. Transplacental infection of pig fetuses with porcine reproductive and respiratory syndrome (PRRS) virus causes segmental or diffuse hemorrhage in the umbilical cords as a result of necrotizing arteritis. Few stillborn fetuses have specific microscopic lesions; lesions are more common in live littermates. Gross lesions include ascites, hydrothorax, and edema of perirenal tissue, splenic ligament, and mesentery. Microscopically, mild to moderate segmental arteritis occurs in the lungs, heart, and kidneys. Alveolar septa in the lungs are thickened by mononuclear cell accumulation and proliferation of type 2 pneumocytes. Aggregates of lymphocytes, plasma cells, and macrophages are present in blood vessels in the heart, portal tracts, and cerebellar white matter. Various degrees of endometritis and myometritis also occur with lymphohistiocytic perivascular cuffs and edema.

Equine viral arteritis virus (an arterivirus) in the mare causes abortion, but in the majority of cases no lesions are in the fetus. In this species, the mechanism is probably fetal anoxia due to compression of uterine blood vessels by virus-induced myometritis, although a few cases of arteritis in the chorion and myocardium of aborted fetuses have been described.

Bunyaviruses, such as Akabane virus and Cache Valley virus, cause fetal infection and abortion in sheep and other ruminants. The virus produces a range of lesions in the developing fetal central nervous system, including hydranencephaly, microencephaly, cerebellar hypoplasia, and loss of spinal cord ventral horn neurons. The loss of ventral horn neurons causes denervation muscle atrophy. The atrophy and myositis are responsible for arthrogryposis (fixation of limb joints) and skeletal deformities, such as torticollis and scoliosis.

Bluetongue virus (Orbivirus) is an important viral infection of the ovine fetus in those areas where the bluetongue occurs. Fetal lambs with this infection develop hydranencephaly as a result of infection with bluetongue virus. They have viral antigen in immature neural cells in areas of necrosis in the periventricular zone of the cerebral hemispheres. Bluetongue is discussed elsewhere.

1299

1300

Fig. 18-39 **Ovine protozoal placentitis, toxoplasmosis, abortion, placenta, sheep.** The cotyledons have hundreds of white foci of necrosis, a lesion that is characteristic of *Toxoplasma gondii* – induced abortion in sheep and goats. (Courtesy Ontario Veterinary College, University of Guelph.)

18.2.1.5.2.4

### Protozoal diseases

*Toxoplasma gondii* is an important cause of abortion in ewes. The organism has a cat-sheep life cycle, with contamination of sheep feed by cat feces. Gross lesions in the fetal membranes include edema of the intercotyledonary chorioallantois and white 1- to 2-mm foci in the cotyledons (Fig. 18-39). A small percentage of fetuses with toxoplasmosis have leukoencephalomalacia that is likely a nonspecific effect of fetal anoxia secondary to placentitis. Microscopically the cotyledonary lesions are distinctive and consist of multiple foci of necrosis with rare groups of toxoplasma organisms within trophoblasts. Immunohistochemistry is particularly useful to detect organisms.

*Neospora caninum* is now recognized as a major cause of abortion in cows. Fetuses are 3 to 9 months' gestational age and have no gross lesions. In the fetal brain, multiple foci of necrosis or proliferated microglial cells are often adjacent to capillaries with hyperplastic endothelium. Groups of *Neospora caninum* in or around these foci are either extracellular or occur in neural cells or endothelial cells. In the heart, the lesions include subacute multifocal epicarditis, myocarditis, endocarditis, and protozoal organisms either in myofibers or endothelial cells. Mononuclear portal hepatitis, multifocal hepatocellular necrosis, and fibrin thrombi in sinusoids are also seen. Foci of mononuclear inflammatory cells are present in additional organs, including the placenta.

*Trichostrongylus axei* in cattle is another protozoal organism that can cause abortion, although it usually causes early embryonic mortality. Mild placentitis, with no fetal lesion, is present. The standard method of diagnosis is the demonstration of protozoa in the contents of the fetal abomasum. Endometritis can be severe, and pyometra is a possible sequela. Infiltration of the endometrium with mononuclear cells is moderate to severe. Lymphoid nodules and secondary follicles develop; these are likely sites of local production of IgA.

Twinning is a common noninfectious cause of abortion in mares. Normally, chorionic villi develop where contact is made between the endometrium and the chorion. In other areas, such as the contact area between chorion and endocervix and the contact area between the placentas of twins, chorionic villi do not develop and the chorionic surface is smooth. Thus the combined functional area of the chorions of both twins is only slightly larger than that for a normal nontwin foal. Twin fetuses often have growth retardation. Aborted twin equine fetuses often appear to have died at different times. Death is thought to be because of placental insufficiency. When the available space in the uterus is divided evenly, which is approximately 80% of cases, both twins usually die and are aborted in midgestation. In cases in which great disparity exists in the apportioning of space, the favored twin has a chance of survival, whereas the other dies and mummifies.

In the mare, endometrial fibrosis, often the result of a previous endometritis, reduces the area of the endometrium available for formation of a diffuse placenta (Figs. 18-16 and 18-35). Chorionic villi do not develop where there is no endometrium with glands for the formation of interdigitations between fetal and maternal parts of the placenta. In large areas of endometrial fibrosis, the chorion does not develop microcotyledons and their villi. Clearly demarcated and smooth areas of chorionic surface mirror the affected areas of the endometrium. Severely affected mares become pregnant but do not carry the fetus to term because the functional area of the placenta is too small.

Premature placental separation in the mare has been described in two forms. One form occurs around the time of parturition, causing the chorioallantois to appear at the vulva with the cervical star intact. Although the caudal part of the chorioallantois is detached from the uterus, the cranial part remains in place, and there is tearing of the chorioallantois across its body. The other form occurs some time before parturition. Prematurely detached areas become brown and dehydrated.

Another equine disease, albeit a rare one, in which fetal death and abortion occur as a result of placental insufficiency and fetal malnutrition is uterine body pregnancy. The fetus occupies the uterine body rather than the body and horns, and the placenta is underdeveloped in the horns.

There are several abnormalities of the equine umbilical cord, including excessive length (or inadequate length) and torsion. In torsion of the umbilical cord, the cord is long, excessively twisted, and the twists are difficult to undo. For a twisted cord to qualify as pathologic, lesions caused by compromise of the umbilical vessels must be present. The cord is edematous and hemorrhagic, and congested distended segments alternate with constricted twisted segments (Fig. 18-40). Fibrin is often present on the surface of affected areas of the cord. Lesser degrees of torsion occur without seriously affecting the umbilical blood vessels and killing the fetus. The urachus is thinner and more pliable than the umbilical arteries or vein and is more easily constricted. Local distentions of the urachus can occur anywhere along its course in the cord from the umbilicus to the allantoic cavity. They are useful in confirming the obstructive effects of torsion of the cord.

1300

1301

Fig. 18-40 **Umbilical cord torsion, equine fetus.** This aborted fetus, wrapped in its amnion, has a very long and twisted umbilical cord. Twisted cords are often longer than 83 cm, a risk factor for torsion of the cord. (Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 18-41 **Adventitial placentation, placenta, choiron cow.** Additional sites of placentation are visible in the intercotyledonary chorion. They appear as red plaques, sometimes with villi, that extend from cotyledons. There is a corresponding change on the endometrium. (Courtesy Drs. W. Crowell and Tyler, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Adventitial placentation in ruminants is the formation of additional placentomas (Fig. 18-41). It is thought to be an age-associated change because more are seen in cows with a higher parity. It is also considered a hyperplastic response to inadequacy of the placentomal surface area. A reduction in the area of placentomes due to loss of caruncles can occur as a result of endometritis, removal of cotyledons during aggressive manipulations, removal of retained placental membranes, and chronic placentitis. Adventitial placentation is also seen in hydroallantois and when fetuses are the result of cloning. Compensation for a reduced placentomal area can be achieved by enlargement of the existing functional maternal caruncles and the establishment of additional areas of contact by simple villous interdigitation. These adventitious areas form initially adjacent to the placentomes but can expand to involve much of the surface.

Just as adventitial placentation may be a “normal” or age-associated change in many situations, so there are structures in the placenta of most species that may be confused with lesions. These are particularly numerous in the mare and are listed in Box 18-6. It is important to know the normal or incidental findings before describing lesions. All species have amniotic plaques (Fig. 18-42, A). They are small raised plaques of epidermal tissue, and some may have hair growing from them. In ruminants they are up to 2 cm in diameter and only on the amnion on the same side as the fetus. Ruminants in particular have mineralization of the placenta, which appears as a white lacy change especially to the chorion. The equine placenta has many others, including normal avillus areas, allantoic pouches, and chorioallantoic pouches. Two structures that often cause confusion are the hippomane and the yolk sac remnant. Almost all equine placentas have a hippomane in the allantoic cavity. These are rubbery concretions of allantoic precipitates that vary in color from white to tan to red (Fig. 18-42, B). Also confused with a lesion or anomaly is the yolk sac remnant. This is a circular cystic structure found in the allantoic portion of the umbilical cord, from the junction of the amnion and the cord to the junction with the chorioallantois. It may be surrounded by the umbilical vessels or extend from the tissue of the cord from a stalk (Fig. 18-42, C). This remnant is often mineralized and, when opened, has a fluid-filled center and an ossified wall. The outer surface is smooth, but the inner surface has a pattern that resembles the inner surface of the calvarium. It is sometimes mistaken for the skull of a twin or an amorphous globosus (see later; Fig. 18-44).

1301

Fig. 18-42 **Incidental structures, placentas.** **A**, Amniotic plaques, bovine fetus and placenta. Multiple white, raised circular plaques up to 1.5 cm in diameter are present on the fetal side of the amnion. They are normal incidental structures composed of stratified squamous keratinizing epithelium. *Inset*: An amniotic plaque (*arrow*). H&E stain. **B**, Hippomane, allantois, equine placenta. These rubbery flattened discs up to 10 cm in diameter are the end result of aggregation of sediments of allantoic fluid in the horse and other equids. They are incidental findings. **C**, Mineralized yolk sac remnant, umbilical cord, equine fetus. Yolk sac remnants seen on the allantoic portion of the umbilical cord are incidental structures. Note that in this case the yolk sac is connected by a stalk containing blood vessels and is located at the junction of the umbilical cord and the allantois. McCracken, College of Veterinary Medicine, University of Tennessee; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C**, Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Hydramnios and hydrallantois refer to the excessive accumulation of fluid in the amniotic and allantoic sacs, respectively. These lesions occur mostly in the cow, are rare, and usually do not occur together. Accumulation of excessive amniotic fluid occurs in association with some fetal facial muscle and skeletal abnormalities. The implication is that serious nervous abnormalities impair the muscles responsible for the fetal drinking reflex. An association has been found between fetal adrenal insufficiency and hydramnios. Allantoic fluid is formed in part from fetal urine received through the urachus. In the cow, hydrallantois occurs in conjunction with adventitial placentation and in some twin pregnancies. Abortion or dystocia follow, with a dead and sometimes small anasarctous and ascitic fetus. The allantoic fluid composition changes from normal to that closely resembling maternal or fetal extracellular fluid. When these membranes are retained after delivery of a fetus, fluid sometimes continues to accumulate.

**Fig. 18-43 Cyclopia, porcine fetus.** A defect of ocular and cranial development has resulted in fusion of the eyes (cyclops) and a proboscis above the eye. Cyclopia can occur in the lambs of ewes that ingest the plant *Veratrum californicum* on the fourteenth day of gestation. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

1302

**Fig. 18-44 Acardiac monster (bovine amorphous globosus).** This structure, covered with hair, is the remnant of a twin fetus and is attached to the placenta of the normal twin by a stalk. It is a rare finding in cattle and is usually of little consequence. (Courtesy Dr. J. Edwards, College of Veterinary Medicine, Texas A&M University; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Fetal anomalies can take innumerable forms. Some of those that directly influence the reproductive process are mentioned here. First, certain anomalies cause prolonged gestation because a fetal adrenal gland does not make the necessary hormonal contribution to the birth process. Alteration of the pituitary-adrenal axis, such as aplasia or hypoplasia of the adrenal glands or anomalies of the anterior pituitary, will prolong gestation. One classic example is prolonged gestation in ewes that ingest the plant *Veratrum californicum* on the fourteenth day of gestation. Along with the cyclopia (Fig. 18-43) and holoprosencephaly that occurs, the pituitary may be absent. Absence of the pituitary gland also occurs, probably as an inherited disease, in Guernsey and Jersey cattle. Absence of the pituitary gland can occur alone or as part of hydranencephaly or anencephaly.

The second large group of fetal anomalies interferes with the reproductive process by causing mechanical problems at parturition (dystocia). Examples are hydrocephalus, hydrops fetus, and arthrogryposis.

Amorphous globosus is a rare and incidental finding in bovine placentas especially. It is a type of acardiac monster, and it is a severely anomalous second fetus. It is usually spherical, covered in hair, and attached to the placenta by a cord (Fig. 18-44). Histologically, various organs can be identified within the structure.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Retention of fetal membranes for longer than normal after parturition is common, especially in the cow. In cows, membranes are considered retained if not expelled by 12 hours postpartum. During normal pregnancy, there is a turnover of maternal epithelial cells of the caruncle. As parturition approaches, there is a gradual loss and flattening of the cells. Trophoblasts compensate by hyperplasia. Normal separation of cotyledon from caruncle involves reduced cell proliferation and increased apoptosis of placental tissue. Parturition before there is complete “maturation” of the epithelium is believed to result in retention of placental membranes; thus retention is common in cases where caesarian section is necessary because there may be insufficient time for complete maturation to occur. Infectious, nutritional, hormonal, circulatory, hereditary, and weather factors may inhibit the “maturation” process. Retained membranes can act as a nutrient medium for growth of contaminant bacteria and for the development of severe endometritis from the transient mild postparturient endometritis. The endometritis can even cause systemic disease, such as septicemia or disseminated intravascular coagulation.

### 18.2.1.6 CERVIX

Disease of the cervix is rare in domestic mammals and is usually part of more generalized disease. There is considerable variation in the anatomy of the cervix, and this has an impact on uterine health because of the function of the cervix.

#### 18.2.1.6.1 Anomalies

Two entire cervixes or a single bifurcated cervix, along with a divided vagina and two uteri, can result from failure of proper fusion of the paired paramesonephric ducts. In cows, some developmental abnormalities are restricted to the cervix. These include hypertrophy or hypoplasia of the whole structure, aplasia of one or more of the usual five rugae, tortuosity, and dilation or diverticulum formation of the cervical canal.

#### 18.2.1.6.2 Degenerative Disease

Ewes exposed to estrogenic substances in subterranean and red clover develop a permanent infertility because of alteration of the cervix. Affected animals have a cervix that has fused cervical folds and uterine-like glands that produce a less viscous mucus. Alteration of cervical mucus affects spermatozoal migration and results in reduced fertility.

#### 18.2.1.6.3 Infectious Diseases

Cervicitis usually occurs as a minor lesion concurrently with more severe endometritis or vaginitis. This distribution is observed in specific infectious diseases, such as contagious equine metritis caused by *Taylorella equigenitalis*, and in nonspecific postparturient metritis, cervicitis, and vaginitis. As a single lesion, inflammation of the cervix can result from poorly performed traumatic artificial insemination. In cows with acute cervicitis, the caudal rugae are edematous and prolapse into the vagina. Inflammatory exudate covers the cervical mucosa and collects in the vagina. The cervical mucosa is relatively thin, and the underlying fibromuscular tissue is relatively impervious to infection; thus most cases of cervicitis resolve readily. Those infections that follow traumatic dystocia are likely to involve the muscle layer from the onset and have the potential to produce severe lesions. These lesions include paracervical abscesses, local peritonitis with granulating tracts into the connective tissue of the pelvic canal, stenosis

---

with adhesions across the lumen of the cervix in areas denuded of epithelium, or cysts filled with mucus in the lining.

### 18.2.1.6.4 Neoplasms

Neoplastic disease of the cervix of domestic animals is very rare.

### 18.2.1.7 VULVA AND VAGINA

The two main categories of disease of the vagina and vulva are similar to those of other parts of the female reproductive tract, being (1) infectious and inflammatory disease and (2) noninfectious conditions, including neoplasia, anomalies, and hyperplasia.

#### 18.2.1.7.1 Inflammatory Disease

Postparturient vulvitis and vaginitis occur when these organs are lacerated during dystocia and become infected. Trauma unrelated to parturition also can progress similarly. Inflammation of the cervix and proximal vagina following dystocia can have a more serious outcome because of the possible local spread of infection into and through the vaginal wall into the peritoneal cavity.

Granular vulvitis describes the clinical appearance of the vulva and vagina in inflammatory diseases. Inflammation causes the red coloration (hyperemia) and exudates, and the granular appearance is to a large extent the result of enlargement of the lymphoid follicles of the region (Fig. 18-45). Thus any infectious agent can be a cause. In bitches, this appearance is relatively common in so-called nonspecific vaginitis or vulvitis. Granular vulvitis in cattle occurs with *Ureaplasma diversum* infection. In the acute stage, there is a profuse purulent vulvular discharge and a hyperemic vulvular mucosa with 2-mm raised granules. The disease can become chronic, and lesions resolve within 3 months. In about 10% of affected cows, discrete, raised, white epithelial inclusion cysts, 2 to 5 mm in diameter, occur in rows or clusters on the dorsolateral wall of the vulva. Infection of cows is usually self-limiting, but herds can have a persistent infection. Bulls and semen can remain infected and spread the infection during mating or artificial insemination. Reduced fertility with return to service or abortion is seen with pathogenic strains of the organism as a sequela to infection and inflammation of the embryo or fetal membranes.

**Fig. 18-45 Granular vulvitis, vulva, cow.** Granular vulvitis is a nonspecific condition resulting from development and hyperplasia of subepithelial lymphoid follicles of the vulva and vestibule. Inflammation of the vulva, in the initial stages, causes hyperemia. There is subsequent hyperplasia of lymphoid tissue, visible as 1 to 2 mm raised white nodules on the vulval mucosa (*upper portion*). It is commonly seen in cows with infection of the vulva or vagina with *Ureaplasma diversum* and results in a granular appearance of the mucosa. (Courtesy Dr. R.B. Miller, Ontario Veterinary College, University of Guelph.)

Infectious pustular vulvovaginitis of cattle is caused by BHV-1, which is similar to the BHV-1 that is the cause of infectious bovine rhinotracheitis (IBR). The two diseases behave as separate entities, but their occurrence can overlap in a herd or in an individual. Vulvovaginitis is transmitted by coitus, artificial insemination, and possibly nose-to-vulva contact. The first evidence of the disease includes hyperemia and edema of the vagina and vulva; these lesions are followed by petechial hemorrhages and slight nodularity of the mucosal surfaces. A rapidly coalescing multifocal erosion and ulceration of the mucosa follows, beginning over the lymphoid nodules (Fig. 18-46). Microscopically, changes can be detected in the epithelium, the lamina propria, and the lymphoid nodules. The epithelium with eosinophilic intranuclear inclusions undergoes ballooning degeneration followed by necrosis, neutrophil infiltration, and desquamation, but without discrete stages of vesicle or pustule formation. The lamina propria is hyperemic, edematous, and infiltrated by inflammatory cells, mostly lymphocytes and plasma cells. The subepithelial lymphoid nodules are hyperplastic. Resolution of the disease is rapid, and the lesions that remain are slightly thickened epithelium and hyperplastic lymphoid nodules. Lesions are similar in the penis of affected bulls.

## Pathologic Basis of Veterinary Disease, 4th Edition

Caprine herpesvirus 1 causes lesions in goats similar to those of bovine vulvovaginitis (Fig. 18-47). In the equine species, equine herpesvirus 3 (as distinct from EHV-1, and responsible for respiratory disease, nervous disease, and abortion) is the cause of coital exanthema characterized by transient vesicles and erosions morphologically similar to those observed in IBR on the external genitalia of both mares and stallions (Fig. 18-48).

1304

1305

### 18.2.1.7.2

#### Noninflammatory Disease

Tumefaction of the vulva is normal during estrus. Overly large or persistent swelling is abnormal. Abnormal tumefaction occurs in hyperestrogenism, such as with estrogen-producing ovarian neoplasms and exposure to estrogenic substances (Fig. 18-49). The vaginal mucosa becomes swollen with edema and protrudes through the vulva, exposing the mucosa. Toxicosis of pigs by the mycotoxin zearalenone found in moldy corn is a cause. Other effects of the mycotoxin are precocious mammary development, tenesmus leading to rectal prolapse, and the luteotrophic activities that induce anestrus or pseudopregnancy.

1305

Fig. 18-49 **Vulva hypertrophy and edema, estrogenic effect, sow.** The vulva of this sow is swollen with edema. This swelling is typical of hyperestrogenism secondary to mycotoxicosis. (Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

Fig. 18-50 **Polyyps, vulva, bitch.** There are several vaginal polyps arising from the wall of the vagina. The larger caudal polyp adjacent to the urethra protrudes caudally through the labia of the vulva and is ulcerated. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Vaginal hyperplasia, hypertrophy, and/or prolapse of bitches is a common disease seen during the follicular stage (proestrus) of the first to third estrus periods in young animals, particularly of the brachiocephalic breeds. These animals are assumed to have an increased sensitivity to estrogen and develop excessive edema. The vaginal mucosa swells and interferes with coitus. Dramatic swelling can, if severe, result in the tissue protruding from the vulval labia to produce a prolapse that becomes excoriated and ulcerated. Spontaneous regression during diestrus is the norm.

Vaginal polyps are relatively common in older bitches (Fig. 18-50). They are usually solitary, up to several centimeters in diameter, and have a thin stalk of attachment to the vaginal wall. Excision is usually curative.

Cysts in the vaginal wall of the cow arise from mesonephric duct remnants (Gartner's ducts) or major vestibular (Bartholin's) glands. Causes of cyst formation include inflammation of the lining of the duct or gland, and hyperestrogenism, in which edema caused by estrogen stimulation is prolonged. Gartner's ducts normally do not open into the vagina. When they become cystic, they form single or multiple cysts or a tortuous channel in the floor of the vagina somewhere between the cervix and near the urethral opening. Major vestibular glands are found on the ventral and lateral walls of the vestibule and become cystic when edema, inflammation, or scar tissue obstructs their openings. Other anomalies include persistent hymen, vaginal septum (double vagina), and stricture or stenosis of the vagina or vestibule that follow traumatic injury at parturition.

### 18.2.1.7.3

#### Neoplasms

Transmissible venereal tumor (TVT) of the dog is transmitted by coitus and the transfer of intact neoplastic cells. TVT cells have 59 chromosomes compared with the normal canine number of 78. Immunohistochemical evaluation with tumor markers suggests that these tumors may have a histiocytic origin, although a complete characterization is not reported. Both sexes are affected. The neoplasm begins as a nodule beneath the genital mucosa and when enlarged breaks through the overlying mucosa. In the bitch, the lesion often begins in the dorsal wall of the vagina at the junction with the vestibule. It proliferates into the lumen of the vagina and can protrude through the vulva as an ulcerated, friable mass (Fig. 18-51, A). Microscopically the neoplastic cells are large, round or oval, and uniform in size (Fig. 18-51, B) but with occasional large, bizarre nuclei. Cytoplasm is poorly defined, is lightly staining, and may have peripheral vacuoles. This neoplasm can spontaneously regress and have multifocal necrosis, infiltration of lymphocytes, likely cell-mediated neoplastic cell lysis, and deposition of collagen. This neoplasm is exquisitely sensitive to vincristine. A few dogs have metastases in other sites, although in countries with stray dogs and dogs in poor health, neoplasms with metastases are relatively common.

Squamous cell carcinoma of the vulva occurs in the mature cow, ewe, and mare (Fig. 18-52). Solar radiation has been established as an etiologic factor. Ewes subjected to the Mules operation (surgery of the perineum and inguinal areas intended to redirect the tip of the vulva to prevent urine wetting the wool) and to short tail docking have a greater exposure of the vulva and greater incidence of squamous cell carcinoma of the vulva. Correlation can be made of incidence with exposure to sunlight and, at least in the cow, with the lack of pigmentation of the vulva. The squamous cell carcinoma originates on the hairless and less pigmented skin of the vulva and has the appearance and biologic behavior of squamous cell carcinomas in other sites. The neoplasm metastasizes late in the course of the disease to the iliosacral lymph nodes.

1306

1307

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Carcinoma of the vulva or vagina in bitches is uncommon. Involvement of the urethra with transitional cell carcinoma and the development of a polypoid neoplasms and masses that extend from the urethral orifice, however, is a recognized entity in bitches and other domestic species.

Bitches develop multiple leiomyomas of the vagina. These only occur in entire bitches, so a hormonal link is proposed. Ovariohysterectomy may be curative, further indicating hormonal dependence. The common differential diagnoses of leiomyoma are vaginal polyps (see previous discussion). These have a similar appearance, and histologic examination is usually required to differentiate them because each has well-circumscribed nodules up to several centimeters in diameter that arise from the vaginal wall (Fig. 18-50).

### 18.2.2 MAMMARY GLAND

#### 18.2.2.1 INTRODUCTION

Mastitis and mammary neoplasia are the major diseases of the mammary gland; most of the others represent aberrations or extreme manifestations of physiologic states.

Mastitis is inflammation of the mammary gland. Galactophoritis is inflammation of the mammary ducts. Most cases of mastitis begin with galactophoritis. Mastitis is the most economically important disease of the mammary glands, and although it occurs in all species, it is a particular problem in animals used for milk production.

Galactostasis is a condition in which the glands become engorged, hot, and painful. It occurs after weaning or in pseudopregnancy. Clinical signs are associated with milk retention, and there is no systemic illness. It is presumed to be the result of inadequate oxytocin release because of fear, stress, or lack of mammary stimulation.

Agalactia is a rare condition, and the cause is unknown. In goats there may be an association with the caprine arthritis and encephalitis virus (CAEV). The udders are hard, but no milk is produced. It is called “hard udder,” and there is usually microscopic interstitial inflammation present.

1307

1308

Galactorrhea (also called inappropriate lactation and precocious lactation) is also unusual and, in bitches, occurs at the termination of diestrus when there is a prolactin surge in response to a reduction in progesterone concentration. It occasionally occurs following ovariohysterectomy during diestrus. Galactorrhea is seen in male goats of high milk production lines.

Inappropriate mammary development and lactation is relatively common in bitches as part of pseudopregnancy and was discussed previously.

#### 18.2.2.2 MAMMARY DISEASE OF DOGS

Neoplasia of the mammary glands is common in the dog, and it has the highest incidence of all domesticated species (Fig. 18-53). Most canine mammary tumors are benign. There has been much interest in canine mammary neoplasia both from the view-point of prognosis and treatment, from a logical pathogenetic viewpoint, and as a tool in comparative oncology. Although the phenomenon of mammary neoplasia is well recognized, the cause is not. There are obvious risk factors, especially desexing at a young age. Ovariohysterectomy after the second estrus dramatically increases the prevalence of this disease. The

## Pathologic Basis of Veterinary Disease, 4th Edition

---

window of susceptibility is up to 2 years of age. A high-protein diet decreases susceptibility, whereas treatment with medroxyprogesterone acetate and being a purebred increases it.

Mammary neoplasms are a diverse group that are dominated by epithelial (and myoepithelial) tumors. Stromal tumors, such as fibrosarcoma and osteosarcoma, are much less common but are particularly aggressive and metastatic. The embryology of the mammary gland involves a close association between the epithelium and mesenchyme, so it is not surprising that tumors are often combinations of stroma and epithelium with the so called complex adenomas having a mixture of epithelial and myoepithelial components, and the mixed mammary tumor having those elements plus cartilage and bone.

**Fig. 18-53 Mammary carcinoma, mammary gland, bitch.** This mammary carcinoma has infiltrated and replaced normal mammary gland and contiguous soft tissue. The upper nodule is the neoplasm, and the lower and surrounding white tissues are composed of infiltrating neoplastic cells and fibrous tissue, the result of a desmoplastic response. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

The development of mammary epithelial neoplasia can proceed from ductal or lobular hyperplasia to dysplasia and on to neoplasia and progression from the benign adenomas and papillomas to carcinoma in situ and to invasive forms (Fig. 18-54). Once progression begins, an individual will often continue to develop neoplasia, and the development of multiple mammary masses is likely. The prognosis for each subsequent mass is not dependent on the previous one, so that many different types of neoplasia can be found in one animal.

Predicting behavior of mammary neoplasms is an inexact science. From a pragmatic and simplistic view, invasion is an indicator of a poor prognosis. It is the reason that excisional biopsy is the best procedure for diagnosis in dogs; cytology can be of use in identifying inflammation and malignant stromal neoplasms but

## Pathologic Basis of Veterinary Disease, 4th Edition

can give a false impression of malignancy. The neoplasms that arise are pleomorphic in their characteristics, and, as such, there are many different classification schemes.

General principles of neoplasia apply, and, in dogs, those that are locally invasive are more likely to be life threatening. The threat increases with the lack of differentiation, and there is an increasing risk of metastasis with tubulopapillary, solid, and anaplastic carcinomas, respectively. Those with metastasis to the local lymph node have an especially poor prognosis. Because there is a potential for progression from benign to malignant, neoplasms (either because of rapid growth or having additional time to develop) larger than 5 cm in diameter have a poorer prognosis.

**Fig. 18-54 Adenocarcinoma, invasion into lymphatic vessels, bitch.** Note the neoplastic cells infiltrating through the wall of the lymphatic (*above left*). Microscopic invasion by mammary carcinoma into a lymphatic, as depicted here, is an indicator of a poor prognosis. In this case, there are lymphocytes and plasma cells in the perilymphatic tissues. H&E stain. (Courtesy Dr. M. Domingo, Autonomous University of Barcelona; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

In dogs, mastitis caused by bacteria or *Mycoplasma* occurs early in lactation or pseudopregnancy. Staphylococci, streptococci, and *Escherichia coli* are major isolates. It is assumed that the pathogenetic pathways of mastitis in dogs is the same as for dairy animals and will be discussed in detail later. Infection of fissures in nipples and adjacent skin spreads via the ducts and lymphatics into the gland and results in suppurative inflammation and/or abscesses. The glands become swollen, large, firm, and edematous because the toxins and tissue destruction by the agents, or the cytokine and contents of inflammatory cell granules, cause acute inflammation. It may be superimposed on mammary hyperplasia or mammary neoplasia, especially on tumors of ducts. Systemic illness is often seen. The effect of mastitic milk on puppies is not known.

### 18.2.2.3 MAMMARY DISEASE OF CATS

Fibroadenomatous hyperplasia (mammary hypertrophy) occurs in young intact female cats. Those less than 2 years old are most likely to develop mammary enlargement, which usually occurs in the spring and with the first several estrus cycles. Much of what is known about this disease is based on its coinciding with the luteal phase of estrus, early in pregnancy or after progestin therapy. High concentrations of progesterone or progesterone-like substances is the common link. As expected, megestrol acetate treatment of an old neutered male or female can induce this also. What is difficult to explain is that not only can all glands be affected, but only one gland, or parts of one gland, may be as well. Occasionally, only nodules may arise. The lesion is the result of notable proliferation of mammary ducts and adjacent stroma (Fig. 18-55). This overstimulation of an otherwise normal process is likely to be the result of a local dysregulation of tissue growth with the stimulation of receptors by progesterone. Some have theorized an exaggerated response to prolactin as well. Hemorrhages, coagulative necrosis, and/or ulceration of affected areas can occur. In young females, resolution is spontaneous or ovariectomy is effective. Older neutered animals on progestin require drug withdrawal and sometimes mastectomy.

**Fig. 18-55 Mammary hypertrophy (fibroadenomatous hyperplasia), mammary gland, cat.** Mammary ducts have proliferated and are surrounded by abundant loosely arranged stromal tissues. Typically, cats with mammary hypertrophy are young and develop enlargement of one or several mammary glands, in the spring. H&E stain. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Mammary neoplasia in cats is relatively uncommon, so studies of causal factors have been limited. There does not appear to be the same relationship with early desexing as there is with dogs. Progression from focal hyperplasia to adenoma to carcinoma is recognized, but this progression is presumably rapid, as many of the carcinomas are small.

## Pathologic Basis of Veterinary Disease, 4th Edition

The majority of neoplasms in cats are carcinomas. They are usually single and occur in the subcutaneous tissue adjacent to the nipple; 75% to 96% are adenocarcinomas and show rapid growth (Fig. 18-56). They metastasize to regional lymph nodes, either the axillary or superficial inguinal nodes, lungs, or other mammae. The average age of affected animals is 10.7 years, and there is a 7- to 9-year-old risk plateau.

1309

Intact animals are at a slightly greater risk, but there is no beneficial effect of early spaying. The poorest prognosis is in older cats with neoplasms that are greater than 3 cm in diameter, with the presence of regional lymph node involvement, with increased number of mitoses, and with the presence of necrosis. Well-differentiated tumors have a better prognosis. The interval between diagnosis and death is often short, less than 1 year, but the range is wide. There is no or only a weak correlation between histologic features, including proliferation indices and prognosis, except perhaps size.

1310

**Fig. 18-56 Mammary carcinoma, mammary gland, cat.** The cells of this anaplastic neoplasm do not resemble those of normal epithelium but are large and round. They are arranged either in clusters or as individual cells within a fibrous stroma. Inflammatory cells, including neutrophils and lymphocytes, are also present. H&E stain. (Courtesy College of Veterinary Medicine, University of Illinois.)

18.2.2.4

### MAMMARY DISEASE OF COWS

Mastitis in dairy cattle is an extremely important disease. Most of the organisms responsible for mastitis are bacteria. The number of bacterial pathogens of the mammary gland are staggering in their number and range of lesions they cause. The majority of cases are caused by *Staphylococcus aureus* and are of the subclinical or moderate clinical forms.

Mammary pathogens can be divided into groups based on the source of infection for other cows. In one group are those organisms such as *Streptococcus agalactiae*, *Staphylococcus aureus*, and *Mycoplasma* sp., for which the mammary gland is the principal site of persistence or reservoir. Coliform organisms are in the

## Pathologic Basis of Veterinary Disease, 4th Edition

group that is acquired from the external environment, such as fecal matter, soil, water, or bedding. An overlap group has members, such as *Streptococcus uberis* and *Streptococcus dysgalactiae*, capable of persisting in either location. Cow-to-cow transmission is important for the mammary reservoir group, whereas contamination of the teat end is important for disease caused by the environmental group. The rates of new mammary gland infections in dairy cows caused by environmental pathogens are greatest during the first and the last 2 weeks of a 60-day nonlactating period. Coliform and streptococcal infections that are established during the nonlactating period with organisms from the environment are present at the time of parturition and cause clinical mastitis soon afterward.

Another way to group the pathogenic organisms is by the disease they cause. The three main groups, based on their virulence and effects including systemic disease, are the gram-negative pathogens, gram-positive pathogens that cause acute severe necrotizing disease, and gram-positive pathogens that cause chronic suppurative mastitis. Gram-negative organisms, particularly *Escherichia coli*, can cause severe mastitis and systemic effects because of endotoxin release. Gram-positive pathogens cause disease that ranges from subclinical mastitis to gangrenous mastitis. Many induce a chronic suppurative disease.

Gram-negative bacteria gain access to the glands and release endotoxins, and the cytokine release they invoke results in necrosis and severe vascular leakage (Fig. 18-57). A systemic acute phase reaction induced by the endotoxins and cytokines results in fever, anorexia, leukopenia, hyperfibrinogenemia, and hypocalcemia. This latter feature can be mistaken for primary milk fever. Edema of the mammary gland and surrounding areas is often prominent. Local changes include necrosis and sequestration of glandular tissue, wherein regions of the gland become dry, friable, and surrounded by a red border of hyperemia and hemorrhage (Fig. 18-58). The massive outpouring of edema fluid causes the gland to be dramatically swollen and hard and the “milk” to be watery and/or contain fibrin that can obstruct the ducts and sinuses. Not only is this type of mastitis potentially life threatening because of endotoxemia, the severe effects on the gland often lead to reduced defenses to other pathogens so that secondary, pus-forming pathogens also proliferate.

1310

1311

**Fig. 18-57 Severe necrotic mastitis, coliform mastitis, mammary gland, cow.** Serum oozes through the dead skin of the affected right rear quarter. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 18-58 Necrotizing mastitis, coliform mastitis, mammary gland, transverse section of quarter, cow.** Note the dry and pale area, typical of coagulative necrosis, to the left of center. The necrotic tissue is partially surrounded by a zone of edema and by a thin light-gray band of fibrous tissue. Encapsulated necrotic tissue is designated a “sequestrum.” (Courtesy College of Veterinary Medicine, University of Illinois.)

Severe acute mastitis is caused when necrotizing gram-positive bacteria, including virulent *Staphylococcus aureus* and streptococci, gain entry to the glands. With severe staphylococcal mastitis, there is neutrophilic infiltration within minutes to hours of introduction, and the products of neutrophils contribute to the necrosis of the glandular tissue. Cell surface-associated (adhesions, protein A, and capsular polysaccharides) and extracellular secretory products (leukotoxins, extracellular enzymes, and coagulase) of these organisms contribute to the damaging effect of these bacteria. The combined result is hemorrhage and necrosis of the gland, with the result that the gland or part of the gland becomes gangrenous, hard, dry, and red-black. When severe, systemic effects of the acute phase response caused by systemic cytokines induce fever, anorexia, weight loss, leukopenia, and hyperfibrinogenemia.

The pus-forming bacteria tend not to produce or induce the degree of necrosis, vascular effects, or systemic effects of the first two groups. These bacteria invoke a neutrophilic response that dominates the lesion and results in the build up of the characteristic necrotic leukocytic debris that typifies the suppurative response. The lesions they induce are often centered on the lactiferous ducts and sinus, and result in the filling of these tubes with suppurative exudate (Fig. 18-59). *Arcanobacterium pyogenes*, *Mycoplasma bovis*, *Streptococcus dysgalactiae* and various aerobes and anaerobes are prime candidates. Nocardial mastitis can be included in this group as well. Infection with these organisms, especially *Arcanobacterium pyogenes*, can occur with long-acting intramammary preparations used in the nonlactating or dry cow period. The occurrence in dry cows, initially recognized in the summer months, led to the name “summer mastitis.” Careful culture of these cases will reveal a mixed culture of organisms and often up to five or six different

## Pathologic Basis of Veterinary Disease, 4th Edition

species of the *Arcanobacterium*, *Streptococcus*, *Bacteroides*, *Peptostreptococcus*, and *Fuso-bacterium* genera. Because these are found in other pyogenic infections, it can be assumed that they are environmental contaminants. Dry cows are often not examined closely, so the mastitis is typically chronic, with thick intramammary exudates and fibrosis. Mycoplasma mastitis is similar in type, but infection can be from a systemic infection. Spread of the organism to calves and resultant otitis, arthritis, and pneumonia can occur.

*Streptococcus agalactiae* was the most important pathogen of the bovine mammary gland in the era before adequate mammary gland hygiene and efficient antibacterial drugs. Resistance of cows to mastitis caused by this organism is subject to great individual variation; in general, resistance decreases with age. The mammary gland is the only organ affected by this organism. *Streptococcus agalactiae* does not persist long in the environment. Once a cow is infected, however, the organism persists in the lactiferous sinus, with periodic waves of multiplication, increase in virulence, and tissue invasion. The initial response to invasion of *Streptococcus agalactiae* is interstitial edema and an influx of neutrophils into the interstitium and alveoli. The alveolar epithelium undergoes either brief hyperplasia or vacuolation and then is desquamated. Macrophages quickly become a component of the cell population of infected alveoli, and fibrosis rapidly obliterates the lumen of these alveoli. Edema, cellular infiltration, and fibrosis are lesions found in infected and adjacent alveoli, so that pressure is increased within the lobule and within adjacent lobules. The increased pressure causes stagnation of milk flow, thereby initiating premature involution of a portion of the gland. After the acute phase, periductal fibrosis occurs and granulation tissue replaces part of the normal cuboidal to columnar epithelium of smaller ducts. Fibrous polyps can completely obstruct milk flow. Restoration of ductal epithelium can occur after the granulation tissue has matured and contracted. The lactiferous ducts and sinuses, with their normally two-layered columnar epithelium, are similarly but less severely affected, often going through a phase of squamous metaplasia of the epithelium.

1311

1312

**Fig. 18-59 Suppurative mastitis, mammary quarter, cow.** The lactiferous sinus and ducts are filled with viscous yellow pus. (Courtesy College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The gross appearance of a mammary gland with mastitis caused by *Streptococcus agalactiae* depends on the stage of the disease; different stages are to be expected in different areas of a gland. Usually more than one quarter of the gland is involved. In the acute stage, hyperemia involves the mucosa of the lactiferous sinus. Milk quality is altered, and strands or clumps of debris are present in the milk, or the milk is transformed into pus. The areas of parenchymal edema and cellular infiltration are gray and turgid. Groups of alveoli, in which the secretion is retained because of obstruction of the duct by granulation tissue, resemble small abscesses. Involuting parenchyma and fibrotic parenchyma appear similar to one another and can be difficult to differentiate grossly. The mucosa of the lactiferous sinus becomes granular and thickened because of underlying projecting areas of granulation tissue and surrounding fibrosis.

Isolates of *Staphylococcus aureus* obtained from the bovine mammary gland range from nonpathogenic to highly pathogenic. The severest form of staphylococcal mastitis is the gangrenous form (Fig. 18-60), usually seen shortly after parturition and involving a variable proportion of the udder. Severe acute inflammation, with classic heat, redness, swelling, and pain, progresses to necrosis with its coldness of the affected area, blue-black color, and fluid exudation.

**Fig. 18-60 Gangrenous mastitis (*Clostridium* sp.), mammary gland, transverse section of udder, cow.** Most of the right quarter and some of the adjacent left quarter are dark red with hemorrhage. A well-demarcated hyperemic border has formed at its junction with the adjacent normal gland (*right udder*). There is also marked subcutaneous edema between the gland and the skin. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

Microscopically, during the first 48 hours after infection with toxigenic *Staphylococcus aureus*, the infected tissue has severe interstitial edema that increases the interalveolar stromal area and reduces the alveolar luminal area. Progressive swelling, vacuolar degeneration, and focal erosion and ulceration occur throughout the duct system and are most prominent near the junction of stratified squamous epithelium and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

columnar epithelium in the area of the papillary duct. The organism attaches to epithelial cells, causing focal damage, and later can be seen on, within, and below ductal and alveolar epithelium. Inflammatory cellular response is rapid, with neutrophils initially in the subepithelial tissues of the distal parts of the duct system, then within the epithelium, and later in the interstitial and epithelial tissue of alveoli.

Staphylococcal mastitis in the less acute form follows a course similar to that of streptococcal mastitis. Initially, damage occurs to the epithelium of the lactiferous sinus and larger lactiferous ducts. Organisms extend rapidly along the ducts and produce acute inflammation in groups of adjacent terminal alveoli. In chronically infected quarters, macrophages are the principal inflammatory cell type in epithelial lining, in lumens, and especially in the glandular interstitium. Lymphocytes also increase in number, but some investigators have reported a lack of increase in plasma cells. These observations suggest that mammary gland lymphocytes could become hyporesponsive to antigenic stimulation in quarters chronically infected with *Staphylococcus aureus*. Some data indicate that mammary gland lymphocyte function is compromised; blastogenesis is depressed in lymphocytes recovered from quarters infected with *Staphylococcus aureus*. Studies have documented that plasma cells are prevalent in the stroma of mammary glands with chronic *Staphylococcus aureus* mastitis; more cells produce IgA than IgG antibodies, and IgA-containing cells increase in number as the disease progresses. The extent of regeneration is uncertain; it is unclear whether damaged alveoli redevelop secretory tissue or remaining healthy tissue undergoes compensatory hypertrophy, or whether both processes occur.

*Staphylococcus aureus* has a greater propensity than *Streptococcus agalactiae* to invade the interstitial tissue between alveoli. The initial inflammatory reaction is necrotizing; abscess formation can follow. Abscesses, scattered and often coalescing, vary in size from those that are microscopic to those grossly visible. Sometimes the staphylococcal organisms are surrounded by rosettes of club-shaped material. (The obsolete term *botryomycosis* was applied to such lesions.) An equally important and parallel set of events occurring in the lobules not invaded by bacteria is the obstruction of milk flow by granulation tissue and pressure from surrounding fibrosis, resulting in involution of those uninvaded lobules. Multiple, small, soft cream to pink nodules, some containing pus, are separated by bands of fibrous tissue. Disease caused by less pathogenic strains of staphylococci, such as nonhemolytic coagulase-negative strains, progresses less dramatically and not necessarily with obvious abscess formation. However, the same components of granulation tissue and fibrosis are present, causing obstruction and pressure, which in turn cause atrophy of adjacent lobules.

1312

1313

Coliform mastitis is caused after organisms from the environment contaminate the opening of the papillary duct at the distal end of the teat and ascend the duct. The most common organisms are *Escherichia coli*, *Enterobacter aerogenes*, and *Klebsiella pneumoniae*. The coliform organisms probably exert their damaging effect via endotoxin acting on the vasculature. In the acute form of the disease, the lesions are hyperemia, hemorrhages, and edema of the affected areas centered around the lactiferous ducts. The secretion in the lactiferous sinus is cloudy and blood stained and has clumps of fibrin (Fig. 18-61). Microscopically, interlobular septa are edematous and fibrin thrombi are in lymph vessels. Epithelium of ducts and alveoli is necrotic, and very few inflammatory cells are present in the alveoli. Coliform organisms are numerous in the alveoli. Large numbers of organisms are phagocytosed by the secretory epithelium. The severity of the disease in postparturient cows is attributed to a delay in the influx of neutrophils. The cow's response to endotoxin is influenced by the stage of the reproductive cycle. The nonlactating mammary gland is much less sensitive to the effects of endotoxin than the lactating gland.

If the cow survives endotoxemia, the necrotic mammary tissue, which can be a large portion of a quarter, becomes separated from the viable tissue and is sequestered or eventually sloughs (Fig. 18-62). Cows in early lactation with less severe coliform mastitis often develop chronic mastitis that has alterations of

## Pathologic Basis of Veterinary Disease, 4th Edition

hyperplasia, disorganization, and filiform processes of the epithelial lining of the papillary duct and lactiferous sinus.

*Arcanobacterium pyogenes* causes a mastitis in lactating, nonlactating, and even immature bovine mammary glands that is characterized by abscesses in the tissue of the small and large lactiferous ducts. Abscesses range from those microscopic in size to those grossly visible. Fistulas from the abscesses can form at the base of the teat. Fibrosis of the abscess walls can result in loss of small unaffected ducts and involution and fibrosis of the parenchyma they drain. The wall of large abscesses is thickened by granulation tissue.

Mycoplasma mastitis in cows occurs as individual sporadic cases or in outbreaks. Several mycoplasmas are capable of causing bovine mastitis, but *Mycoplasma bovis* is by far the most prevalent. The disease caused by *Mycoplasma bovis* can affect one quarter or involve the whole gland. Experimental inoculation of one quarter will often spread to all quarters. Hematogenous spread and contamination of the teat are therefore routes by which the gland becomes infected. Affected quarters initially are enlarged, firm, and light brown and have a nodular parenchyma. The nodules are abscesses that can be up to 10 cm in diameter. Exudation of neutrophils into the lobular interstitium and alveoli is intense in the early stages. The exudate changes with chronicity to include mononuclear cells. Early vacuolation and degeneration of alveolar epithelium is followed by hyperplasia of alveolar and ductular epithelium, and then by metaplasia to a relatively undifferentiated multilayered epithelial lining. Focal erosions of duct epithelium are filled in by granulation tissue. Aggregates of lymphocytes occur in the lobular interstitium and around ducts. Interstitial fibrosis and lobular atrophy are found in the late stages.

1313

1314

**Fig. 18-61 Coliform mastitis, mammary gland, cow.** There is marked thickening of the walls of the lactiferous ducts. White to yellow fibrin and pus have collected in the lactiferous ducts and the upper portion of the lactiferous sinus. (Courtesy College of Veterinary Medicine, University of Illinois.)

**Fig. 18-62 Sloughed quarter, mammary gland, necrotizing mastitis, cow.**

The necrotic right rear quarter has recently sloughed, leaving a large ulcerated area covered by a thin gray layer of exudate. The surface is finely granular, indicating the formation of granulation tissue. (Courtesy College of Veterinary Medicine, University of Illinois.)

Granulomatous mastitis in the cow generally occurs when drugs for the treatment or prevention of mastitis are introduced through the teat and are contaminated with *Nocardia asteroides*, *Cryptococcus neoformans*, atypical *Mycobacterium* sp. (other than *Mycobacterium bovis*), or *Candida* spp. These infectious agents can also cause spontaneous mammary gland disease from organisms normally existing in the environment. Nocardial mastitis is the best known of these diseases because it occurs in outbreaks. Severely affected cows develop pyrexia that may last for several weeks. They become lethargic and lose weight, as would be expected with cytokine release. The glands are hot and swollen and may have multiple abscesses or granulomas. Small white particles may be found in the exudate. Lesions in the glands are centered on the lactiferous ducts and sinuses, as galactophoritis (inflammation of these structures) is the prominent finding. Because the infection is chronic and ascending, lobules are affected to a varying degree. Granulomas and pyogranulomas predominate microscopically. These are usually surrounded by fibrous tissue, and extensive involvement results in the gland being replaced by a framework of fibrous tissue surrounding pockets of inflammatory cells and central necrotic debris (Fig. 18-63). An udder affected with cryptococcal mastitis has the same yellow gelatinous material that is typical of cryptococcal lesions elsewhere.

### 18.2.2.5

#### MAMMARY DISEASE OF SHEEP AND GOATS

There are two main agents recovered from the mammary gland of sheep: *Mannheimia hemolytica* and *Staphylococcus aureus*. In many sheep flocks, the main manifestation of infection with these agents is unexpected death, because these bacteria are responsible for an acute necrotizing or gangrenous mastitis. It is difficult to be certain, but the morbidity can be about 5% and mortality 20%. Mastitis in goats is similar,

## Pathologic Basis of Veterinary Disease, 4th Edition

and as with the disease in sheep, is assumed to have a similar pathogenesis as the disease in cattle. *Mycoplasma agalactiae* or *Mycoplasma mycoides* ssp. *mycoides* are usually the causative agents.

Goats develop a manifestation of infection with CAEV that causes “hard udder.” This disease is seen in herds with CAEV infection, and affects does in the first few days of lactation. The udder is hard, and little milk can be expressed from the teat. Recovery occurs, but milk production is reduced. The pathology of this disease is not fully described, but histologically there are large numbers of lymphocytes and lymphoid follicles in the interstitium between the glands. The virus grows in mammary epithelium and is present in milk. The newborn is infected through infected milk. A similar disease is seen with infection with the ovine lentivirus of the maedi-visna virus complex that is responsible for the diseases of ovine progressive pneumonia and the neurologic disease ovine lentiviral encephalitis or visna. This chronic lymphoproliferative disorder affects many organs, the mammary gland being one.

**Fig. 18-63 Chronic mastitis and galactophoritis (*Nocardia* spp.), mammary gland, transverse section, cow.** Chronic inflammation of the lactiferous ducts and adjacent mammary gland has resulted in the replacement of most of this gland by pyogranulomas and abscesses containing yellow pus. The adjacent normal glandular tissue has involuted. This cow was infected when the dry cow medication was contaminated by *Nocardia* spp. (Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph.)

## 19 Chapter 19 Male Reproductive System\*

ROBERT A. FOSTER

The reproductive system is arguably the most important in terms of survival of a species. In production animals, reproduction is essential for the continued supply of product, be it meat, fiber, milk, or any of the many other by-products. Most production animals rely on a small number of males as breeding stock, so in addition to being 50% of the reproductive team, an infertile male or one carrying an undesirable trait can have a major impact.

The male reproductive system usually receives little attention and time; with some exceptions, replacement of a breeding male is often more effective than diagnosis and treatment. Fertility in the male is difficult to reverse unless the cause can be readily found and then corrected. This is where knowledge of the processes, responses to injury, and prognosis are so important.

Companion animals have not been given the same amount of study as production animals, especially the bull and ram. The aim here is to emphasize the diseases of all species and highlight the mechanisms and reactions of the male reproductive tract by examining the diseases of each anatomic location.

### 19.1 INTRODUCTION

#### 19.1.1 ORGANIZATION OF THE MALE REPRODUCTIVE SYSTEM

The male reproductive tract can be separated into three major areas based not only on anatomic location but also on functional characteristics and on important disease processes. The three main areas are the scrotum and its contents, the accessory genital glands, and the penis and prepuce.

##### 19.1.1.1 THE SCROTUM AND CONTENTS

The purpose of the scrotum and its contents is to supply spermatozoa for transportation to the female. Although the general focus is on the testis and its germinal epithelium contained in the seminiferous tubules, other parts have important functional characteristics that allow this to happen. Testicular development is quiescent until puberty when spermatogenesis begins. The testes therefore are small until puberty, when they increase to their adult size. The testes are covered by a tunica albuginea, which is relatively nonexpansile and usually maintains the testicular contents under slight pressure. Within the testis are the interstitial and intratubular regions. Within the interstitium are the interstitial endocrine cells, blood vessels, lymphatics, and occasional macrophages. Each seminiferous tubule has a lining of myoid cells and a limiting membrane. There is a basement membrane between these structures. The arrangement of the seminiferous tubules varies from species to species, but the end result is the formation of spermatozoa. After spermatogenesis, spermatozoa are transported through rete tubules into the efferent ductules and then into the epididymis, a single and extremely long duct. In doing so, the spermatozoa mature and are concentrated. The pathway out of the scrotal area is through the ductus deferens.

The purpose of the scrotum, tunica vaginalis, and the spermatic cord (ductus deferens, pampiniform plexus, and cremaster muscle) is to protect and maintain spermatogenesis at a temperature slightly lower than body temperature. The testes are raised or lowered, according to ambient temperature, by the cremaster muscle. There is a counter current vascular system that allows the testes to be at a lower temperature than body

## Pathologic Basis of Veterinary Disease, 4th Edition

temperature; the pampiniform plexus assists this process. The pulsatile nature of arterial blood flow is altered in this process to form a continuous but lower pressure system. In addition, the scrotal skin, which is thin, often hairless, and in most species has abundant apocrine sweat glands, helps to maintain a lower testicular and epididymal temperature. The tunica vaginalis, being an outpouching of the peritoneum, allows for free movement of the testes within the scrotal sac. The scrotum is composed of skin, tunica dartos, and scrotal fascia. It is fused with the parietal layer of the tunica vaginalis. The skin has a thin dermis, few hairs, and many apocrine sweat glands.

\* Previous contributions to this chapter were authored by Dr. H. Acland of the Pennsylvania Veterinary Laboratory, Harrisburg, Pennsylvania.

### 19.1.1.2 THE ACCESSORY GENITAL GLANDS

The purpose of the accessory glands is to provide nutrition and a transport medium for spermatozoa. There are four main accessory glands: the ampullae, vesicular glands, prostate, and bulbourethral glands. There is considerable species variation in the size, type, and number of these accessory glands. Ruminants and horses have all four glands, although the prostate of ruminants is either very small (bull) or is disbursed within the pelvic urethra (ram and buck). Pigs lack ampullae, dogs have only a prostate, and cats have a small prostate and bulbourethral glands. The secretion of the vesicular gland and prostate is serous, but the bulbourethral gland typically has a viscous mucoid product.

### 19.1.1.3 THE PENIS AND PREPUCE

There is considerable structural difference between the penis and prepuce of the various species. In prepubertal animals, the prepuce is attached to the penis, but they become separated at sexual maturity. The penis of the horse is erectile and is located within a prepuce that produces a thick, waxy material called smegma. Ruminants and pigs have a long fibrous penis that has some erectile tissue. To accommodate a penis of sufficient length, there is a series of bends called the sigmoid flexure, and there is retractor muscle to hold the penis in the prepuce. There is an extension of the urethra in small ruminants that is called the vermiform appendage or the urethral process. This, during ejaculation, spins and sprays semen onto the cervix. The glans of the penis of the boar has a corkscrew shape that allows it to insert into the cervix. The penis of dogs and to a lesser extent cats is erectile and has an os penis. The cat has projections of penile epithelium called spines or barbs on its penis, and they are testosterone dependent.

### 19.1.2 CELLS OF THE MALE REPRODUCTIVE SYSTEM

The function of the male reproductive system revolves around the production and transportation of spermatozoa. Spermatozoa are formed from germ (stem) cells by a process of spermatogenesis. Spermatogenesis occurs in three stages, the proliferative, meiotic, and spermatogenic stages. The proliferative phase involves the mitotically active spermatogonia. They are present at the periphery of the seminiferous tubules on the basement membrane. The second phase is the meiotic phase, in which spermatocytes are formed. In the spermatogenic phase, spermatids and finally spermatozoa are formed. Spermatozoa have a head, body, and tail. The head contains the nucleus and an acrosome, which contains enzymes required for the penetration of the zona pellucida. The body or midpiece contains mitochondria and the tail is a flagellum.

Sertoli cells provide support, nutrients, and other environmental factors to allow spermatogenesis to happen. During spermatogenesis, the cells pass into a region that is separated from and external to the immune system of the body. The barrier is called the blood-testis barrier, and it is maintained by the Sertoli cells (Fig. 19-1).

## Pathologic Basis of Veterinary Disease, 4th Edition

Control of spermatogenesis is achieved through a combination of both central (luteinizing hormone [LH] on the interstitial endocrine cells and follicle-stimulating hormone [FSH] of Sertoli cells) and local (paracrine factors, including testosterone) factors, and there is considerable crosstalk between germ cells, Sertoli cells, and interstitial endocrine cells. Local modification to spermatogenesis is achieved through apoptosis at any stage of development. Many of the diseases and conditions that affect spermatogenesis increase or decrease the apoptotic rate.

1318

1319

**Fig. 19-1 Schematic diagram of the normal components of the testis.** The Sertoli cells, germ cells, and interstitial endocrine cells are closely integrated, and considerable messaging occurs between them. The blood-testis barrier is at the level of the Sertoli cells, with contributions from the myoid cells and basement membrane. Spermatogonia are on the interstitial side of the blood-testis barrier.

The cells lining the various ducts, including the rete tubules, efferent ductules, and epididymides, are epithelial cells that have a variety of functions in addition to being a barrier. Absorption, phagocytosis, and secretion are

## Pathologic Basis of Veterinary Disease, 4th Edition

---

all part of their physiologic role. Movement of spermatozoa along these ducts and tubules is achieved through smooth muscle contraction and the cilia.

In the accessory genital glands, storage of spermatozoa (particularly in the ampulla, where present) and secretion of various substances are the major roles for the epithelium of these glands. From the pelvic urethra and through the penile urethra, the lining cells are urothelial in type.

19.1.2.1

### RESPONSES OF THE MALE REPRODUCTIVE SYSTEM TO INJURY

Injury to the male reproductive system comes in many different forms, and there are many potential targets, including the pituitary and endocrine control, interstitial endocrine cells, Sertoli cells, spermatogenic epithelium, and the various ducts. Apart from the obvious redundancy of having bilateral systems, the male reproductive tract has very little functional reserve and cannot undergo compensatory change to any significant degree. Some testicular compensatory hypertrophy is possible and will be discussed later in this chapter.

The formation of spermatic granulomas (Fig. 19-2) is one of the most dramatic and important responses of the male reproductive system to injury. Spermatic granulomas occur with rupture of a duct; spermiostasis and spermatocele are the usual preliminary stages. Spermatozoa are “foreign” to the body. Immunity to spermatozoa with the formation of antisperm antibody is a well-recognized phenomenon. Exposure of tissue to spermatozoa results in a dramatic local inflammatory response. The cell wall constituents and the high chromatin content make them very difficult to degrade. Any injury that exposes spermatozoa to the tissue of the body results in severe inflammation, mostly of a granulomatous type. This can be a foreign body type response, an immunologic response, or both. The inflammation produced is usually chronic and results in severe scarring, which further obstructs tubules and ducts, leading to even more inflammation so that it becomes self-perpetuating. It is therefore critical to prevent such injury.

Injury to the testis can be the result of a primary attack on a target cell or may be secondary to interruption of hormonal regulation, be it systemic or local. The end point of an injury can therefore be far reaching. Regardless of the primary target, most injurious events result in germ cell degeneration and depletion. Germ cells are sensitive, but Sertoli cells are relatively resistant to injury. As a result, severe injury will often result in seminiferous tubules containing only spermatogonia and Sertoli cells. As Sertoli cells degenerate, they become vacuolated and swollen. Exfoliation of normal germ cells can also occur. The spermatogenic epithelium responds to injury by increasing or decreasing apoptosis, resulting in spermatogenic arrest or a complete failure of spermatogenesis. As long as spermatogonia remain, spermatogenesis can restart. Failure of release of spermatozoa is an early indication of degeneration. The formation of multinucleated spermatid giant cells and phagocytosis of spermatozoa by Sertoli cells occur.

1319

1320

Fig. 19-2 **Spermatic granulomas, tail of the epididymis, ram.** **A**, The parenchyma has been replaced by a white-tan, semiliquid spermatic granuloma. These granulomas may be any color from white to red. They are frequently and incorrectly called abscesses. **B**, Multiple encapsulated (chronic) spermatic granulomas with white caseous centers. **C**, A mass of spermatozoa free in the interstitium (*upper*) is surrounded by epithelioid macrophages and multinucleated giant cells, some of which have phagocytosed spermatozoa. Lymphocytes, plasma cells, and fibrous connective tissue surround these granulomas (*lower*). H&E stain. (**A** and **B**, Courtesy Drs. P. W. Ladds and R. A. Foster, James Cook University of North Queensland. **C**, Courtesy Dr. R. A. Foster Ontario Veterinary College, University of Guelph.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

A major effect of injury to interstitial endocrine cells is the failure of the release of testosterone. This can effectively stop spermatogenesis by increasing apoptosis and by inhibiting maturation of spermatids. Direct damage to spermatozoa can affect motility and fertilizing capability. Recovery from injury, while taking time, is achieved by restarting spermatogenesis from the relatively resistant spermatogonia.

The testis is a specialized immunologic environment and has a reduced immune responsiveness, no doubt because of the importance of not developing an immunologic response to germ cells. Unfortunately, if an inflammatory response does occur within the testis, it is likely to be sustained.

Injury to the epididymis can have permanent and devastating effects. Not only can injury affect the functions of the epididymides—including maturation and storage of spermatozoa, resorption of fluid, and secretion of materials—but also severe injury will result in inflammation. Any constriction of the epididymal duct will result in spermiostasis, potential rupture, and the formation of spermatic granulomas. Because the epididymis is very limited in its responses, alteration to the structure and function of the epididymis is often permanent and affects fertility in a dramatic fashion.

Injury to the accessory genital glands is not common, and they can recover, often with a reduced function. Functional reserve is often sufficient to maintain fertility.

The peritesticular tissues, in particular the tunica vaginalis, is also prone to injury from peritoneal reactions secondary to epididymal disease or from a direct penetrating injury. The reaction of these tissues is identical to that of the peritoneum, and as such, fibrosis and adhesion are a common response. Adhesion can limit the movement of the testes and alter its ability to thermoregulate.

### 19.1.3 PORTALS OF ENTRY INTO THE MALE REPRODUCTIVE SYSTEM

There are three main portals of entry of infectious and injurious agents to the male reproductive tract (Box 19-1). They include direct penetration and injury, ascending infection, and hematogenous localization.

The external location of the penis, prepuce, and scrotum makes them prone to direct penetrating injury. Surprisingly, this is a relatively rare occurrence.

#### 19.1.3.1 Box 19-1 Portals of Entry to the Male Reproductive System

Direct penetration

Ascending infection

Hematogenous localization

Peritoneal spread

Ascending infection is relatively common. It occurs sporadically in adults but curiously is particularly a problem in pubertal animals when hormonal changes make the system more prone to infection from bacteria (such as *Actinobacillus seminis* and *Histophilus somni*) that are resident flora of the prepuce of sheep. The

## Pathologic Basis of Veterinary Disease, 4th Edition

---

accessory genital glands in particular are targets, but there can be further ascension to the epididymis. It is exceedingly rare, because of the long length of the epididymis, for the testis to be involved in ascending infection. The male reproductive tract is also a target of pathogens that are spread by sexual activity. Spread from females or in some circumstances from other males is recognized.

Hematogenous localization is a recognized portal of entry by specific pathogens, such as the various brucellae. The epididymis and the accessory genital glands are particular targets.

The tunica vaginalis is an extension of the peritoneum, being an outpouching of the peritoneal cavity. Any process affecting the peritoneum, be it infectious or neoplastic, will affect the peritesticular tissues.

### 19.1.4 DEFENSE MECHANISMS OF THE MALE REPRODUCTIVE SYSTEM

The male reproductive tract, and in particular the internal genitalia, is so exquisitely sensitive to injury that it is extremely important to prevent rather than respond to injury. The combined effect of the high antigenicity of spermatozoa and the exceedingly long and very narrow duct system means that there is little tolerance for inflammation, necrosis, or other injurious situations. Much of the reproductive system relies on isolation for protection and the prevention of infection or injury.

#### 19.1.4.1 INNATE IMMUNITY

There are multiple factors that prevent infection and injury to the vulnerable tissues. The testes and epididymides are hidden from the external environment by their intrascrotal location and by the extremely long and narrow tube that connects them to the outside world. The thin luminal diameter and extreme length of the ductus deferens makes ascending infection unlikely. There is almost continuous flow of fluid along the ductus deferens and the epididymis, and so the flushing action is protective. Even the accessory genital glands are protected by the flushing action of urine and by the extremely long length of the urethra in species such as ruminants and the pig.

1320

1321

Testicular and epididymal fluid has antibacterial properties. The high chlorine content may be partially responsible. Antimicrobial proteins in seminal plasma are numerous and include bovine seminalplasmin, lactoferrin, and  $\beta$ -defensins. Most of these are acquired in the epididymis, where they are bound to spermatozoa. There are also numerous cytokines normally produced in the tract. Epithelial cells of the reproductive tract have physical barrier proteins, including mucin, that prevent infection.

Nonspecific cellular defenses are relatively few. Neutrophils are not normally present in seminal plasma but can infiltrate rapidly if required. Macrophages are present within tissue and particularly within the testes, where they are recruited and maintained by the interstitial endocrine cells. Their presence inhibits immune response (by producing tolerance). Little is known of the presence of natural killer cells in the male reproductive tract.

#### 19.1.4.2 ADAPTIVE IMMUNITY

Much of the reproductive tract can produce an adaptive immune response if called upon to do so. Where it is important is in the more distal portions of the tract, particularly the accessory genital glands and the prepuce. Unfortunately, development of an adaptive response in the testis and the epididymis is often “too little, too late.” Also, development of adaptive responses in the testis is inhibited by local immunosuppressive factors. This does not, however, prevent adaptive immunity from developing in the

## Pathologic Basis of Veterinary Disease, 4th Edition

testis. The epididymis and ductus deferens do not have a developed mucosal immune system, but there is evidence that such a system exists in the accessory genital glands, particularly the ampulla and bulbourethral glands. When infection occurs, local immunity and transfer of serum immunoglobulin is present. Preputial immunity is also mediated by local humoral and cellular mechanisms. Immunoglobulin G (IgG)- and IgA-based systems are present. Little is known of cell-mediated immune mechanisms in the male reproductive tract.

Using local immunity to protect against infectious disease, particularly those important sexually transmitted diseases, has had little success. Response to vaccination has been variable with some individuals having protective immunity, particularly with *Campylobacter fetus* infection in bulls. Systemic immunity to reproductive disease has also been of variable effectiveness. Although protecting against systemic infection, challenge to the reproductive tract has in some instances increased the response to the infection and caused more damage than would normally occur.

19.1.4.3

### INFLAMMATION OF THE MALE REPRODUCTIVE SYSTEM

In general terms, inflammation of the male reproductive tract is similar to that of other systems. What is unique about the male genital tract is inflammation to spermatozoa. Spermatozoa and germ cells outside the blood-testis barrier are antigenic. There are also antigenic components within seminal fluid. Spermatozoa have antigens that attract immune cells, and they also nonspecifically bind immunoglobulin. These reactions can have a minimal effect on the tissues directly and act by agglutinating spermatozoa or by opsonization. In some instances, the effect is much more dramatic and immunization against spermatozoa can result in a severe inflammatory response. This inflammation can be local or spermatozoa can be “attacked” in those areas where the tissue-spermatozoal barrier is the weakest. In many species, this is the region of the efferent ductule and the epididymis. This so-called autoimmune reaction to spermatozoa can be experimentally created, but a clinical correlate is infrequent. Local effects, however, are much more recognized. Direct damage to testicular parenchyma can result in granulomatous inflammation centered on the seminiferous tubules, the so-called intratubular orchitis. Where spermatozoa are exposed to the tissues of the body, the reaction is that of granulomatous inflammation. Macrophages and multinucleate giant cells are found adjacent to spermatozoa (Fig. 19-2, C). Initially at least, CD4<sup>+</sup> T cells are abundant. Immunoglobulin-producing cells, particularly IgG-containing cells, are found. Granulomas are formed with the characteristic appearance of layers of epithelioid macrophages with multinucleate giant cells and then lymphocytes and plasma cells with a surrounding of fibrous tissue. In advanced cases, inspissated spermatozoa are found within a fibrous capsule. The production of a fibrous capsule and resultant contraction leads to further obstruction to the various ducts and tubules, with the result that additional spermiostasis, spermatocele, and spermatoc granuloma formation continues. This inflammation therefore has devastating effects on fertility. Further complications occur if spermatozoa are released into the cavity of the tunica vaginalis because a severe periorchitis develops and results in fibrosis and the lack of ability to adequately thermoregulate the testes.

19.2

### DISEASES OF THE MALE REPRODUCTIVE SYSTEM

There are many different ways to approach diseases of the male reproductive system (see [Appendix 19-1](#)). Each approach has its own advantages and disadvantages. Some of the diseases affect more than one region, yet there are many diseases that have a primary manifestation in one or more areas. Approaching diseases from a pathogenetic viewpoint is logical; however, it does not always account for clinical relevance or assist in the correlation between clinical signs and prognosis. We will approach diseases based on their anatomic location, that being scrotal contents, accessory genital glands, and the penis and prepuce, because this is more clinically

1321

1322

## Pathologic Basis of Veterinary Disease, 4th Edition

---

relevant. Before doing so, it is prudent to examine ambiguous sexual development because this forms a distinct category.

### 19.2.1 ANOMALIES, INTERSEX, AND AMBIGUOUS DEVELOPMENT

There are a large number of anomalies of the male reproductive system ([Box 19-2](#)). Some have clinical relevance and others do not. Differentiating between these is very important. Some of the anomalies represent the most common disease of a particular species. Where this is the case, the disease will be handled under diseases of a particular anatomic location because this is the most clinically relevant place. We have attempted to divide the various anomalies into those that are major and minor based on effects on fertility and on the future breeding potential of the animal. Some anomalies have a genetic basis and such individuals should not be used as a stud animal, even though the animal may still be fertile.

#### 19.2.1.1 Box 19-2 Selected Congenital Anomalies

##### 19.2.1.1.1 MAJOR ANOMALIES

Cryptorchidism

Testicular hypoplasia

Spermatic granuloma of the epididymal head

Ambiguous genitalia

- Persistent Müllerian duct syndrome
- Testicular feminization syndrome

Immotile cilia syndrome

Segmental aplasia of mesonephric duct

##### 19.2.1.1.2 MINOR ANOMALIES

Inclusion cysts

Remnants of mesonephric ducts

- Paradidymis interna and externa

Remnants of paramesonephric (Müllerian) ducts

- Appendix testis
- Cystic uterus masculinus

Hypospadias

Retained preputial band

19.2.1.2

### MALE EMBRYOLOGY

In males, the differentiation of a gonad to a testis is dependent on the presence of a sex-determining region of the Y chromosome (SRY) that codes for a testis-determining factor and on other genes that cause the germ cells to go into mitotic arrest. Supporting cells become the Sertoli cells, the steroid-producing cells become the interstitial endocrine cells of Leydig, and the mesenchyme develops the appearance of a testis. Further development requires the activation of many other genes that are not on the Y chromosome. The expression of SRY occurs briefly in the somatic cells of the indifferent gonads (or genital ridges). Because expression ceases shortly before Sertoli cells can be recognized, it is proposed that the functional gene product of SRY influences other genes, such as Sox9, that ensure the differentiation and maintenance of Sertoli cells. Sox9 is up-regulated in XY individuals just before gonadal differentiation. Sertoli cells signal the other supporting cell precursor lines to differentiate along the male pathway. Early in sex differentiation, the embryo has a double set of ducts. The paramesonephric (Müllerian) ducts are female precursors, arising by invagination of the celomic cavity. The mesonephric (Wolffian) tubules and ducts are male precursors, arising from the primitive kidney, the mesonephros. The rete testis and efferent ductules are derived from mesonephric tubules. There are about 20 efferent ductules, although the number varies with species. The epididymis is derived from the part of the mesonephric duct within the mesonephros. The ductus deferens, ampulla, and vesicular gland are derived from the distal part of the mesonephric duct, outside the mesonephros (Fig. 19-3).

After germ cells migrate from the yolk sac and the testes develop in the tissue of the genital ridge, the testes produce two hormones. Sertoli cells secrete the polypeptide hormone Müllerian-inhibiting substance (MIS) during embryonic development and at lower concentrations postnatally. MIS causes regression of the ipsilateral paramesonephric duct, indirectly through action on mesenchymal tissue. Sertoli cells stimulate differentiation of interstitial endocrine cells from the cells of the interstitium. Interstitial endocrine cells secrete the steroid hormone testosterone, which causes persistence and differentiation of the mesonephric ducts. Testosterone is likely transported down the mesonephric ducts rather than moving by simple diffusion. A third hormone, dihydrotestosterone, which is a metabolite of testosterone, is required for formation of the prostate gland, the closing of the urethral folds, and the formation of the penis and scrotum. The enzyme steroid 5 $\alpha$ -reductase is produced by cells in the urogenital sinus, genital tubercle, and genital swellings and reduces testosterone to dihydrotestosterone. Functional androgen receptors on target tissues are necessary for androgen-dependent differentiation and growth. Species differences exist in whether the production of testosterone by interstitial endocrine cells is under the control of gonadotropin produced by the fetal pituitary gland or the placenta. Fetal interstitial cells are replaced by postnatal interstitial cells, which are relatively quiescent until puberty. The production of testosterone is regulated by

1322

1323

## Pathologic Basis of Veterinary Disease, 4th Edition

LH, which is under the control of LH-releasing hormone (LHRH) from the hypothalamus. Also under the control of LHRH is FSH, which is produced by the anterior pituitary gland. FSH regulates the activity of Sertoli cells and can thus influence MIS production. Sertoli cells stimulated by FSH produce a glycoprotein, androgen-binding protein, which fosters high testosterone concentration around the germ cells for the progression of spermatogenesis.

**Fig. 19-3 Schematic diagram of the normal components of the male reproductive system and the embryonic structures, especially the mesonephric (Wolffian) duct and urogenital sinus and tubercle, from which they were derived.** The rete tubules and efferent ductules are formed from the mesonephric ductules; the epididymis, ductus deferens, ampullae, and vesicular glands form from the mesonephric duct; the prostate and bulbourethral glands form from the urogenital sinus; and the penis, prepuce, and scrotum form from the genital tubercle and swellings.

The external genitalia form when the genital tubercle is masculinized by the presence of androgens. Elongation of the tubercle forms the phallus; opposing urethral folds form the penile urethra; and the genital swellings fuse to form the scrotum.

### 19.2.1.3

#### TESTICULAR DESCENT

The testes and epididymides undergo descent from their original location to the scrotum. There are two main phases in testicular descent: the intraabdominal and the inguinal-scrotal phases. The developing gonads are held in place by cranial and caudal ligaments. The caudal ligament, the primitive gubernaculum testis, attaches the developing testis to the site of the inguinal canal. It develops into an intraabdominal and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

extraabdominal part that protrudes into the scrotum. Evagination of the peritoneum forms the inguinal canal and the tunica vaginalis.

With the intraabdominal phase particularly, stimulation of gubernaculum mesenchymal cells may be controlled by a low molecular weight factor that resembles the insulin-like peptide hormone INSL3. The receptor for INSL appears to be LGR8. Other molecules are also involved. Exposure to estrogen-like compounds will inhibit testicular descent. The exact mechanisms are yet to be elucidated, but they will no doubt be complex and involve an interrelationship of systemic and local factors.

The inguinoscrotal phase of testicular descent is mediated by the hypothalamopituitary-induced production of gonadal androgens. Having said this, domestic animals with failure of testicular descent into the scrotum seldom have hypogonadotropic hypogonadism. Other factors, such as a balance between androgen receptors and estrogen receptors, affect the genitofemoral nerve, and calcitonin gene-related proteins or binding sites might be involved.

### 19.2.1.4 MAJOR ANOMALIES

The most common and important major anomaly of the male reproductive system is failure of testicular descent, or cryptorchidism. Testicular hypoplasia and segmental aplasia of the epididymis are a close second. These diseases and conditions will be discussed further under diseases of the testis. Much less common, but nevertheless important, are other diseases of sexual ambiguity and intersex.

1323

1324

#### 19.2.1.4.1 Sexual Ambiguity and Intersex

Errors of chromosomal, gonadal, or phenotypic sex are usually manifested by abnormalities in sexual dimorphism. Many of the abnormalities result in a female phenotype and are mentioned in more detail in [Chapter 18](#). We will deal with those diseases that involve genotypic males, animals that have male gonads, or predominantly phenotypic males. One cannot always tell the underlying cause of sexual ambiguity by examining phenotype or even identifying the gonadal type. Complete definition of an anomaly requires knowledge of all three components: chromosomal, gonadal, and phenotypic types.

Sex chromosomes can be abnormal in structure or number. Two examples of abnormal structure of the Y chromosome are deletion of the short arm and isochromosome formation (duplication of one arm and loss of the other). Affected individuals have a female phenotype and extremely hypoplastic gonads. A few cattle have been identified with an isochromosome Y. With duplication of one of the sex chromosomes in an individual with a Y chromosome (XYY or XXY), or a mosaic (as occurs with the calico or tricolor male cats), the external genitalia are male in character. Klinefelter's syndrome (XXY) is discussed under testicular hypoplasia. Chimeras, such as XX/XY, are phenotypically sexually ambiguous, and the degree depends on the relative amounts of each chromosome.

Animals with an XY genotype may have an abnormality of gonadal sex. Hermaphrodites have abnormal gonads, and the gonads possess both testicular and ovarian tissue. There can be a separate testis and ovary, or one or both gonads can be mixed. The mixed organ is termed an ovotestis. Some ovotestes have an end-to-end arrangement of ovarian and testicular tissue, with clear demarcation between the two. Others have central testicular tissue with a periphery of ovarian structures. Bilateral hermaphrodites have an ovotestis on each side; unilateral hermaphrodites have an ovotestis on one side; and lateral hermaphrodites have a testis on one side and an ovary on the other. The genital tract in hermaphrodites is ambiguous. Hermaphrodites occur in canine, porcine, and caprine XX sex reversals and bovine

## Pathologic Basis of Veterinary Disease, 4th Edition

---

freemartin XX/XY chimeras. In many other cases, the basic mechanism for the production of hermaphrodites is unknown.

Sex reversal is the term used when the gonad is not the type corresponding to the XX or XY chromosomal makeup of the individual. XX males have been identified in several species, and they have a testis-determining region on another chromosome. They are discussed under the female system. XY females are rare, but they have been identified in mice, horses, and human beings and have a deletion or mutation of the testis-determining region of the Y chromosome. XY females have hypogonadotropic hypogonadism with no secondary sexual characteristics. The gonad is a streak of ovarian stroma.

Male pseudohermaphrodites have abnormalities of phenotypic sex. Individuals that are clearly male with respect to their chromosomes (XY) and gonads (testes), but whose reproductive tract's phenotypic appearance is ambiguous, are termed male pseudohermaphrodites (Figs. 19-4 and 19-5). The differentiation of the tract can be slightly or greatly abnormal. In many cases, the mechanism for the abnormal differentiation is unknown. Ample scope exists for deficiencies in enzymes, hormones, or receptors to cause imperfect differentiation of the tract to match the gonads.

Three such syndromes in which the pathogenesis is understood are persistent Müllerian duct syndrome (PMDS), androgen insensitivity, and steroid 5 $\alpha$ -reductase deficiency.

PMDS is a rare disorder of Müllerian inhibitory substance (MIS) production or function. MIS can be absent or present in affected human beings, with the syndrome being a result of either a mutation in the MIS gene or the MIS gene receptor. In animals, the syndrome is described in miniature schnauzer dogs with an autosomal recessive mode of inheritance, and in a goat with unknown mode of inheritance.

Affected dogs have XY (or XXY) chromosomes and externally are normal males with the common exception of unilateral or bilateral cryptorchidism. The testes, however, are attached to the cranial ends of uterine horns. When a testis has descended into the scrotum, the uterine horn passes through the inguinal ring. Ductus deferentes can be found microscopically within the myometrium. The cranial vagina and the prostate gland are often present. MIS is present in the testes of normal male dogs up to 143 days of age. MIS is present in the testes of young affected dogs also and is bioactive. A mutation in the structural gene for the MIS receptor results in MIS resistance in PMDS-affected dogs. Dogs with unilateral or bilateral scrotal testes can be fertile. Sertoli cell tumor, hydrometra, and pyometra are diseases to which PMDS-affected dogs are subject. Testicular abnormalities in PMDS, such as reduced spermatogenesis and tubular sclerosis, could be attributable to cryptorchidism. Cryptorchidism could be due to interference with the MIS-controlled first phase of the function of the gubernaculum, the phase in which the testis migrates to the inguinal area.

1324

1325

Fig. 19-4 **Male pseudohermaphrodite, external genitalia, boar.** This pig has a scrotum and intrascrotal testes, but the penis is small and clitoris-like and has a terminal urethral opening (ventral to the tail). (Courtesy Dr. D. Dodd; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 19-5 Male pseudohermaphrodite (male feminization syndrome), reproductive tract, ram.** This sheep has testes, ductus deferentes, and accessory genital glands but also a vulva and a prominent clitoris. An androgen receptor defect would explain these anomalies. (Courtesy Ontario Veterinary College, University of Guelph.)

Deficiency of 5 $\alpha$ -reductase type 2, inherited as an autosomal recessive trait in human beings, has not yet been documented in animals, but in all likelihood exists. The enzyme converts testosterone to dihydrotestosterone, which is required for the masculinization of the urogenital sinus, tubercle, and genital swellings. Without dihydrotestosterone, these structures become caudal vagina, vestibule, clitoris, and vulva. Internally, mesonephric structures (ductus deferens, epididymis) develop. The testes are likely to be retained.

Androgen receptor disorders are becoming increasingly recognized as causes of male pseudohermaphroditism. Most cases are due to a mutation in the androgen receptor gene, which is located on the X chromosome and thus in a single copy. Hundreds of mutations have been identified, and the effects range from complete androgen insensitivity with female external genitalia (testicular feminization) (Fig. 19-5) to mild male pseudohermaphroditism. Affected individuals are chromosomally male and have testes. The testes produce testosterone, but the stimulation of the mesonephric system is not normal because of defective androgen receptors. The normal androgen receptor has a hormone-binding and a DNA-binding domain; once activated by androgen, the domain changes shape and is able to bind to specific DNA sequences and regulate the transcription of other specific genes, leading to normal male differentiation. In human beings with androgen insensitivity, the gene is rarely deleted, but numerous point mutations in the receptor gene have been identified, mostly in the hormone-binding and DNA-binding domains. Whether the result is partial or complete androgen insensitivity depends on the location of the mutation and the change in function of the receptor. Dihydrotestosterone binds to the androgen receptor with greater affinity than that of testosterone, and the

## Pathologic Basis of Veterinary Disease, 4th Edition

receptor, when it acts as a transcriptional factor, might interact with different genes other than the testosterone-bound receptor. In domestic animals, complete androgen insensitivity has been described in the equine, bovine, and feline species. The testes are often cryptorchid and are in the inguinal area. The first phase of testicular migration is normal. The inguinoscrotal second phase, which is under the control of androgens, does not occur. MIS produced by the testes causes regression of the paramesonephric ducts. External genitalia are female in complete androgen insensitivity, with a cranial blind end to the vagina, and neither the paramesonephric nor mesonephric ductal system is present.

19.2.1.4.2

### Segmental Aplasia of Mesonephric Duct Derivatives

Segmental aplasia of the structures of mesonephric ductal origin (epididymis, ductus deferens, ampulla, or vesicular gland) can involve any of the structures but most commonly involves the epididymis alone (Fig. 19-6), and less commonly other structures. Segmental aplasia is reported mainly in the bull and most commonly involves the body and tail of the epididymis and is unilateral. Its inheritance is thought to be autosomal recessive. Spermatozoa become impacted because the epididymal duct is blind ending; local dilation or rupture occurs secondarily, allowing escape of spermatozoa and formation of spermatic granulomas.

1325

1326

**Fig. 19-6 Segmental aplasia, epididymis, dog.** There is no tail of the epididymis of the right testis. This portion of the mesonephric duct did not develop. The left testis is normal. (Courtesy College of Veterinary Medicine, University of Illinois.)

19.2.1.4.3

### Immotile Cilia Syndrome

One or more of several defects in the axoneme of cilia throughout the body and of the flagellum of spermatozoa causes immotile cilia syndrome, a rare disease identified in human beings, dogs, pigs, mice, and rats. An autosomal recessive mode of inheritance is proposed. In dogs, heterogeneity of ultrastructural abnormalities of microtubule doublets and their dynein arms or central microtubules is reported. The effect on the reproductive system is immotile or hypomotile spermatozoa caused by flagellar lesions or to oligospermia (a subnormal concentration of spermatozoa) or azoospermia (no spermatozoa), presumably because of defective cilia in the epididymis and ductus deferens. Because of defective cilia in the nasal mucosa, bronchial and bronchiolar mucosa, and ependyma, commonly associated lesions are rhinitis, bronchopneumonia, bronchiectasis, and hydrocephalus. Also associated is situs inversus, but the pathogenesis of the reversal of the normal left and right orientation of organs is unclear. Female infertility is related to defective function of cilia of the uterine tube.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 19.2.1.5 MINOR ANOMALIES

There are a myriad of minor of anomalies and they are of little consequence except when they are confused with other conditions that do affect fertility. Foremost of the minor anomalies are the various cysts that occur as a result of duplication or failure of regression of embryonic ducts and tubules.

#### 19.2.1.5.1 Cysts of the Male Tract

It is often difficult to identify the origin of an individual cyst or group of cysts. In many instances, anatomic location is the determining factor. Many of the cysts are simply called “inclusion cysts” (Fig. 19-7). These have a wall of compressed collagen, a thin lining of flattened cells, and a clear fluid content. They are found where mesothelial cells are trapped adjacent to a serosal surface. Inclusion cysts attached to the head of the epididymis are good examples.

**Fig. 19-7 Congenital inclusion cysts, testis and epididymis, ram.** These 7-mm cysts (*arrows*) in the tissue between the head of the epididymis and testis are incidental findings and are not significant. (Courtesy Drs. P. W. Ladds and R. A. Foster, James Cook University of North Queensland.)

The testis is derived from gonadal cords that form between the gonadal ridge on the medial side of the mesonephros and remnants of mesonephric tubules. The rete testis and efferent ductules are derived from mesonephric tubules. Within the mesonephros, many mesonephric tubules enter the single mesonephric duct. It is from the within the mesonephric part of the duct that the epididymis is derived. The ductus deferens, ampulla, and vesicular gland are derived from the more caudal part of the mesonephric duct, outside the mesonephros. In the developed testis, about 20 efferent ductules are found, but the number varies with the species. Efferent ductules normally link in the head of the epididymis. Blind efferent ductules result when there is no connection to the epididymis and can be resorbed or persist and enlarge to form cysts or rupture. Blind-ending efferent ductules can be present in sufficient numbers to cause spermiostasis, spermatocele, and spermatic granulomas. The condition known as spermatic granuloma of the epididymal head (SGEH; see later discussion) is thus formed.

## Pathologic Basis of Veterinary Disease, 4th Edition

Unconnected with the lumen of the epididymal duct and efferent ductules, remnants of tubules of the mesonephros can form cysts adjacent to the head of the epididymis (paradidymis externus) or within the head of the epididymis (paradidymis internus). Cysts, both connected and unconnected with the ductular system, are lined by ciliated columnar epithelium. They are clinically significant if they become large enough to cause stasis of spermatozoa in adjacent structures, or if they rupture and liberate spermatozoa into the surrounding tissue. Of no clinical significance is the remnant of the paramesonephric duct, called the appendix testis, located on the cranial or cranioventral surface (depending on the species orientation of the testes) of the testis near the head of the epididymis. Sometimes this small nodule of tissue can appear cystic. A similar cystic structure is found in the band of tissue between the ampullae. It is called the cystic uterus masculinus (Fig. 19-8). Some prostatic cysts of dogs have a similar origin.

1326

1327

**Fig. 19-8 Cystic uterus masculinus, accessory genital glands, ram.** This sheep has a 1-cm thin-walled cyst in the tissue between the ampullae of the ductus deferentes (*arrow*). (Courtesy Drs. P. W. Ladds and R. A. Foster, James Cook University of North Queensland.)

### 19.2.2 DISEASES OF THE SCROTUM AND CONTENTS

The approach to the diseases of the scrotal contents is based on a clinical approach where the scrotal skin, then the vaginal tunics are examined before the testis and epididymis. The most important diseases, though, are those that affect the testis and epididymis. We should not forget the importance of diseases of the scrotal skin

## Pathologic Basis of Veterinary Disease, 4th Edition

and tunics, if not for their direct effects on thermoregulation, but also because they can be confused with disease of the testis, epididymis, or spermatic cord.

19.2.2.1

### THE SCROTUM

The fusion of the paired primordia of scrotal skin depends on hormones produced by cells of the gonad after it has differentiated into a testis. Disturbances in the formative stages can lead to various defects in the scrotum, such as failure of fusion, cleft formation, or bifurcation of the scrotum. Defects can be local, confined to the scrotum and penis, or part of a wider range of defects in an intersex animal. Hypospadias, where the urethra opens on the ventral side of the penis, can be part of these anomalies.

**Fig. 19-9 Frostbite, scrotum, ram.** The skin of the lower portion of the scrotal sac has sloughed. The ventral scrotal skin is alopecic, or covered by crusts from previous frostbite. (Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

Dermatitis of the scrotal skin is common. Often it is nonspecific or involved in generalized dermatopathies. Dermatitis restricted to the scrotum can be the result of trauma, frostbite (Fig. 19-9), or exposure to environmental irritants, such as cement dust. Some pathogens have the scrotum as a predilection site. These include *Dermatophilus congolensis* and *Besnoitia besnoiti* in the bull, and *Chorioptes bovis* in the ram (Fig. 19-10). The heat generated in scrotal dermatitis can interfere with the thermoregulatory function of the scrotum, leading to testicular degeneration.

Neoplasms of any of the types that occur in the skin can occur in the scrotum, but are much less common in the scrotal skin. Neoplasms occasionally encountered are mast cell tumors, melanomas, and hemangiomas in the dog and papillomas in the boar. Testicular tumors occur in the scrotum of previously castrated males, presumably from cells inadvertently transplanted at surgery. Vascular abnormalities, which are probably hamartomas, occur on the scrotum of the boar and dog. The scrotal veins of bulls sometimes become varicose.

1327

1328

### 19.2.2.2 TUNICA VAGINALIS

The tunica vaginalis is the extension of the peritoneum that lines the scrotal sac as the parietal layer and covers the testis, epididymis, and spermatic cord as the visceral layer. The cavity between the two layers is continuous with the peritoneal cavity. The tunics and the cavity thus are subject to all the diseases of the peritoneum and peritoneal cavity. Neoplastic lesions are uncommon; mesothelioma is the most frequently encountered. Parasitic disease, especially the cysts of *Cysticercus tenuicollis* in rams occurs periodically and can be confused with cysts or spermatic granulomas.

Inflammation of the tunica vaginalis as part of a systemic disease, such as feline infectious peritonitis, will have the characteristics of that disease. Inflammation of the tunica vaginalis without initial inflammation of the abdominal peritoneum can be the result of trauma or infection. The latter is likely to be an extension from epididymitis. Especially well-known causes are *Brucella ovis* and *Actinobacillus seminis* in rams, and trypanosomes in bulls, rams, and male goats. In general, traumatic inflammation of the tunica vaginalis is mild and focal, and inflammation with an infectious cause is severe and diffuse. Adhesions between the parietal and visceral tunica vaginalis, also called periorchitis, are fibrinous at first and later fibrous.

### 19.2.2.3 TESTIS AND EPIDIDYMIS

The testis and epididymis are inseparable, and disease of one usually results in disease of the other. Scrotal palpation is the main clinical method for identification of abnormalities of this region, and the changes in size are usually the most obvious. We will therefore approach disease from a size approach, beginning with those that cause small scrotal contents, then with those that result in enlargement of one or more of the intrascrotal structures (Box 19-3).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Missing or aplastic components are rare. Segmental aplasia of the mesonephric duct, usually aplasia of the epididymal tail (Fig. 19-6), is one example. It is described earlier under major anomalies. If one side of the scrotal contents is missing, unilateral castration may have been performed or the affected animal may have been a unilateral cryptorchid. The maldescended testis and epididymis subsequently descended, or the castration operator may have missed a testis and epididymis. Affected sheep, for example, often have had the scrotum removed and the testis is located beneath the underlying skin. A lack of both sides of the scrotal contents can represent castration or bilateral cryptorchidism and requires additional investigation, including measurements of hormonal concentrations, especially after treatment with gonadotrophin-releasing hormone, or surgical exploration. Searching for secondary characteristics that are testosterone dependent, such as the barbs on the penis of the cat, and the presence of a prostate in dogs, can be of assistance in separating behavioral characteristics from similar behaviors in incompletely castrated males.

### 19.2.2.3.2

#### Cryptorchidism

A small testicular size is of great importance, especially to production animals, as daily sperm output is correlated to testicular volume and weight. A small size indicates hypoplasia or atrophy. It can be extremely difficult to differentiate these unless there is a history of size change. Hypoplasia is a congenital condition in which the testis does not increase to its full size at puberty. It is often seen as part of other syndromes, most commonly cryptorchidism. Cryptorchidism is incomplete descent of the testis (normal testicular descent is discussed earlier). In most mammalian species, the testis normally has descended into the scrotum by the time of birth. Cryptorchidism is more often unilateral than bilateral, with the side being somewhat species dependent. Many maldescended testes are on the right side. In the horse, the distribution of maldescent is equally distributed left to right, and in the bull, cryptorchidism usually affects the left side. The undescended testis can be anywhere along its path from caudal to the kidney (Figs. 19-11 and 19-12, A) to the scrotum, including just inside the inguinal ring and just outside the inguinal ring, but not in the scrotal sac. Epididymal differentiation is coordinated with testicular descent, and consequently, epididymal differentiation is slowed in many cases of cryptorchidism.

1328

1329

**Fig. 19-11 cryptorchid testis, intraabdominal, dog.** The retained testis and epididymis (*right*) are hypoplastic (small). The other descended testis (*left*) is normal. (**A**, Courtesy Dr. R.A. Foster, Ontario Veterinary College, University of Guelph. **B**, Courtesy Dr. J.A. Ramos-Vara, College of Veterinary Medicine, Michigan State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Cryptorchidism is the most common disorder of sexual development in the dog and cat; it occurs in as many as 13% of male dogs. It may have a genetic basis and a reasonable working hypothesis is a sex-limited autosomal recessive mode of inheritance. It has been suggested that one gene might control internal testicular descent, and placement of the epididymis and ductus deferens and another gene might control external testicular descent.

In the horse, left and right testicular retention are almost equal in occurrence and the left retained testis is more likely to be abdominal than inguinal in location. Three breeds (Percheron, American saddle horse,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

and American quarter horse), ponies, and crossbred horses were significantly overrepresented in a large hospital-based study of cryptorchidism.

Abnormalities in the gubernaculum could cause cryptorchidism by its failure to develop, improper positioning, excessive growth, or failure to regress. Some other possible predisposing or contributing factors for cryptorchidism include testicular hypoplasia, estrogen exposure in pregnancy, breech labor compromising blood supply to the testes, and late closing of the umbilicus, delaying the ability to increase abdominal pressure.

1329

Atrophy occurs in the cryptorchid testis after puberty. The testis is small and fibrotic and has interstitial collagen deposition, hyaline thickening of the tubular basement membranes, and degeneration of germinal epithelium so that only a few spermatogonia remain along with the normal complement of Sertoli cells (Fig. 19-12, B). Spermatogenesis is dependent on the relatively cool scrotal temperature. Apoptosis (programmed cell death) of germ cells in the higher temperature environment of the abdomen is probably mediated by the regulatory protein p53. Interstitial endocrine cells appear relatively more numerous than in descended testes.

1330

Cryptorchid testes are much more prone to neoplasia than scrotally placed ones. In the dog, Sertoli cell tumors are more likely to occur in the testes present in the abdomen (Fig. 19-13), whereas seminomas tend to develop more commonly in inguinally placed testes. The contralateral testis is also at increased risk for developing a neoplasm, even if the testis is located in the scrotum. A retained testis, especially if enlarged by a neoplasm, is prone to torsion.

Sexually ambiguous or intersex individuals (both hermaphrodites and pseudohermaphrodites) commonly have cryptorchid testes. The greater the ratio of testicular to ovarian tissue, the more likely an ovotestis will have descended into the scrotum. A testis most often lies in the scrotum, and an ovary is in its normal position. The ovary or ovarian portion of an ovotestis is histologically normal, but the seminiferous tubules of a testis or ovotestis are abnormal because of a combination of cryptorchidism and the effects of estrogen produced by the ovarian tissue. Except for a few cases of scrotal testes, the tubules of testis or ovotestis are lined by Sertoli cells with only rare spermatogonia.

**Fig. 19-13 Sertoli cell tumor, cryptorchid testis, dog.** The testicular parenchyma has been replaced by a white multilobular neoplasm. The texture is firm, indicating fibrosis. This dog had bilaterally retained testes and epididymides and bilateral Sertoli cell tumors. (Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

### 19.2.2.3.3

#### Hypoplasia

Hypoplasia of the testes is a very common condition, and it is often present in anomalies such as cryptorchidism and sexual ambiguity. We will deal specifically with the condition of hypoplasia of the testis and epididymis in an otherwise normal male.

It is difficult to distinguish hypoplasia from testicular atrophy by using morphologic features. Both testicular hypoplasia and atrophy can occur alone, with no apparent contributing or influencing factors; either can also be associated with, secondary to, or part of some other lesion. Testicular and epididymal hypoplasia ([Fig. 19-14, A and B](#)) has been causally related to poor general nutrition, zinc deficiency, specific genes in the Swedish red and white breed of cattle, and endocrine and cytogenetic abnormalities. Endocrine disturbances causing testicular hypoplasia are those related to reduced production of either luteinizing hormone by the pituitary gland, which in turn influences testosterone production by the interstitial endocrine cells, or follicle-stimulating hormone by the pituitary gland, which stimulates the nurturing function of the Sertoli cells.

A wide range of cytogenetic abnormalities, from translocations and mosaics to nondisjunctions causing polysomies of sex chromosomes, result in testicular hypoplasia. The best known example of polysomy is

## Pathologic Basis of Veterinary Disease, 4th Edition

the XXY karyotype of Klinefelter's syndrome seen in tricolor cats, bulls, dogs, boars, and stallions. In cats, the syndrome is recognized in males with the tricolor, tortoise shell, or calico coat types. These cats can be XXY, XX/XXY, or more complex chimeras or mosaics with two or more X chromosomes and one or more Y chromosomes. The gene for black and the gene for orange are carried one per X chromosome, and so a normal male cat should not have hair of both colors.

Hypoplasia of the testis can theoretically occur when the number or length of seminiferous tubules is reduced, or when there are no or insufficient germ cells. Usually before puberty, the seminiferous tubules have only Sertoli cells and spermatogonia (Fig. 19-14, *B*). At puberty, the tubules of hypoplastic testes undergo an irregular progressive sclerosis and become collagenous. Interstitial endocrine cells appear to be hyperplastic and clumped.

Hypoplasia of the testes is not apparent until after puberty. Unilateral hypoplasia is more common than bilateral hypoplasia, but this difference in prevalence could be a reflection of the relative ease of recognizing a size abnormality when the normal is available for ready comparison. Unilateral hypoplasia is difficult to explain because most of the causes seem to act systemically and therefore should produce a bilateral effect.

1330

1331

**Fig. 19-14 Bilateral hypoplasia, testes, yearling ram. A,** Both testes and epididymides from this yearling ram are very small compared with normal age-matched controls. **B,** The seminiferous tubules are lined only by Sertoli cells, and there is no spermatogenesis. H&E stain. (*A* and *B*, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

The size range of a hypoplastic testis generally is from a prepubertal size (Fig. 19-14, *A*) to almost normal. The consistency of a hypoplastic testis is near to normal. The severity of the hypoplasia can be graded histologically by the proportion of hypoplastic tubules scattered through the organ. Hypoplastic tubules have a small diameter, are lined by Sertoli cells and a few stem cells and spermatogonia, have a thickened basement membrane, and are surrounded by collagen. Interstitial endocrine cells appear proportionally more numerous, but this is only because the tubular area is reduced and the relative amount of interstitium is increased. In severe testicular hypoplasia, most or all of the tubules are abnormal; the tubules have a small diameter and a uniform microscopic appearance with only infrequent vacuolation of Sertoli cells and without a thickened basement membrane. In moderate hypoplasia, fewer

## Pathologic Basis of Veterinary Disease, 4th Edition

---

tubules are small, those of normal size have some differentiation of the seminiferous epithelium, and a few tubules reach an advanced stage of development. In most tubules, however, when the stage of spermatocyte formation is reached, the spermatocytes undergo degeneration, leaving tubules lined by Sertoli cells with a vacuolated cytoplasm. The lumen of such tubules can contain cellular debris and multinucleate cells that are formed when dividing cells fail to separate. When hypoplasia is mild, only a few small tubules are lined mostly by Sertoli cells, whereas most of the tubules are active, many producing spermatozoa. Multinucleate spermatid giant cells can be present in the tubular lumens of some of these testes. Mild hypoplasia is difficult to distinguish from testicular degeneration. The number of hypoplastic tubules would not be expected to increase with age because hypoplastic tubules do not arise after puberty.

19.2.2.3.4

### Testicular Atrophy

Testes that reduce in size after puberty are atrophic, and the microscopic change is degeneration of the seminiferous tubules. Testicular atrophy is a relatively common lesion. Mild testicular degeneration can be detected only microscopically, but when it is severe and chronic, the testis is small and firm (Fig. 19-15). The causes are many, and in a particular individual, the specific cause is often unknown. Degeneration can be unilateral or bilateral, depending on whether the cause is local or systemic. In young growing males, the distinction between testicular degeneration and hypoplasia is often difficult to make using morphologic features. Both lesions are often present together because hypoplastic testes are prone to degeneration. Inflammation also can be superimposed on degeneration when there is obstruction, leading to back pressure, rupture of seminiferous tubules, and spermatic granuloma formation. Recovery of a testis with degeneration back to a normal testis is possible if the injurious agent is eliminated and damage is not too severe.

Specific causes of testicular degeneration are numerous (Box 19-4), and accumulating data indicate that many agents act via apoptosis of germ cells. Fever or local heat from inflammation of the scrotal skin is a classic cause of degeneration. Obstruction of flow of spermatozoa causes testicular degeneration. Obstruction can be due to developmental anomalies such as segmental aplasia of mesonephric duct derivatives, local injury, or inflammation of the epididymis. Vascular events, such as impairment of aging, torsion, or severe crushing of the spermatic cord, will cause degeneration. Systemic injurious factors include nutritional deficiency, hormonal aberrations, toxins, and irradiation. Hypovitaminosis A and zinc deficiency are specific nutritional deficiencies; general malnutrition also causes testicular degeneration. Interference with gonadotropin-releasing hormones, or luteinizing hormone and its control of androgen production by interstitial endocrine cells, or follicle-stimulating hormone and its effect on the production of androgen-binding protein by Sertoli cells can have a deleterious effect on the seminiferous epithelium. Such interference could happen, for instance, when a neoplasm of the pituitary gland causes local compression of the pituitary gland, the hypothalamus, or both. Estrogen produced by Sertoli cell tumors induces testicular degeneration. Some therapeutic drugs, such as amphotericin B, gentamycin, and chemotherapeutic compounds, cause testicular degeneration.

1331

1332

**Fig. 19-15 Unilateral testicular atrophy and epididymitis, testis and epididymis, ram.** The affected testis (*right*) is small, and testicular veins are not visible on the tunica albuginea due to fibrosis and contraction of the connective tissue. The other testis (*left*) is bulbous, indicating hypertrophy. (Courtesy Drs. P. W. Ladds and R. A. Foster, James Cook University of North Queensland.)

Of the many toxins capable of causing testicular degeneration, most damage the spermatogonia and dividing primary spermatocytes, but some damage later stages, spermatocytes and spermatids, or injure Sertoli cells. Degeneration of seminiferous epithelium can occur secondary to injury of Sertoli cells.

A testis undergoing degeneration initially is softer than normal, and as the degeneration progresses, the testis becomes smaller. The cut surface of the normal testis and the acutely degenerated testis bulges slightly. After the acute phase, the testis becomes firmer and has small flecks or large areas of mineralization, especially in ruminants. Degeneration can be either generalized or regional, occurring in the dorsal part of the testis (near the head of the epididymis) in rams or in the ventrum of bulls. If the degeneration is due to ischemia after a vascular accident in the spermatic cord, small islands of parenchyma can survive the infarction because of diffusion of oxygen from vessels of the epididymis and

1332

1333

tunica albuginea. Degeneration can occur locally around a lesion, such as a neoplasm, that expands and causes compression.

Microscopically, testicular degeneration has similar features to testicular hypoplasia; small seminiferous tubules with a thickened basement membrane, decreased numbers of germinal cells, vacuolated Sertoli cells, intratubular giant cells, and interstitial fibrosis (Fig. 19-16, A and B). The vacuolation of the Sertoli cells is likely to be more severe in the testis undergoing degeneration than in testicular hypoplasia because of the degeneration of Sertoli cells and the loss of germinal cells. A key lesion in the differentiation of testicular degeneration from testicular hypoplasia is the wavy basement membrane found in testicular degeneration because affected tubules had at some stage reached full size and then subsequently collapsed. Because the basement membranes are thickened, they can be seen without special staining. At the end stage of testicular degeneration, Sertoli cells are the only lining cells

## Pathologic Basis of Veterinary Disease, 4th Edition

remaining, but with time, these also disappear, leaving only the basement membranes. Mineralization can involve intratubular cellular debris, tubular basement membranes, or the interstitium.

Fig. 19-16 **Testicular degeneration, testis. A, Ram.** There is interstitial fibrosis that separates the seminiferous tubules. Spermatogenic arrest at the spermatocyte stage, vacuolation of Sertoli cells, and a wavy basement membrane due to a reduction in tubular diameter are present. H&E stain. **B, Dog.** In addition to reduced spermatogenesis, there is formation of multinucleated spermatids (*centrally*) as a result of failure of spermatids to separate. This is a common change in testicular degeneration. (**A** and **B**, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Degeneration of the epididymis is less well studied but does occur. In degenerative conditions, the epididymis is much less likely to be reduced in size. This lack of reduction in size can be helpful in differentiating testicular atrophy from hypoplasia. In the former the epididymis will approximate adult size, whereas in hypoplasia the epididymis is also small in size.

19.2.2.3.5

### Epididymitis and Spermatic Granulomas

There are several diseases that result in testicular and epididymal enlargement. Foremost is inflammation, especially epididymitis, and testicular neoplasia.

Spermatic granuloma of the epididymal head is a unique disease of most species that is congenital in origin. It is not an infectious condition, but inflammation predominates as a response to extravasated spermatozoa. It affects the efferent ductule region first, and then spreads to involve the head of the epididymis (Fig. 19-17, A). All efferent ductules should link in the head of the epididymis, but blind-ended efferent ductules result when there is no connection with the single epididymal duct. At puberty, the blind-ending ductules fill with spermatozoa and the resultant spermiostasis can proceed to formation of a spermatocele, and spermatic granulomas (Fig. 19-17, B). These progress over time and result in infertility because of obstruction. The back pressure produced by the spermatic granulomas causes dilation of the mediastinum of the testis and testicular atrophy.

Epididymitis is very important in rams (Fig. 19-18) and dogs (Fig. 19-19) and is rare in other species. The tail of the epididymis is almost always affected, allowing the majority of cases to be differentiated from spermatic granuloma of the epididymal head. Because the epididymis is only a single coiled tube, any lesion along its length has potential for causing obstruction of spermatozoal flow and for the formation of spermatic granulomas. Thus epididymitis is frequently accompanied by spermatic granulomas and periorchitis. Epididymitis can be focal or multifocal or diffuse, unilateral, or bilateral. It is most frequently encountered in unilateral, chronic, focal, or multifocal form and thus can be recognized by comparing the size and shape of the abnormal organ with the normal one. In acute inflammation, the epididymis is soft and swollen; in chronic inflammation, it is firm and enlarged because of the deposition of fibrous tissue and likely to be nodular because of the distention of segments of the duct and the presence of spermatic granulomas. Epididymitis is one of the causes of testicular degeneration. The testis on gross appearance is atrophic. Focal fibrinous or fibrous adhesions occur between the visceral tunica vaginalis over the epididymis and the parietal tunica vaginalis lining the scrotal sac (Fig. 19-18). If a spermatic granuloma ruptures into the cavity of the tunica vaginalis, diffuse inflammation of the tunics can result, followed by adhesions across the cavity (Fig. 19-20). In some cases, fistulas discharge through the scrotum.

1333

1334

Fig. 19-17 **Spermatic granuloma, head of the epididymis, dog.** **A,** The head of the epididymis is tremendously enlarged because of spermatic granulomas (*white-yellow masses*). The body and tail of the epididymis (*vental*) are small, as the spermatic granulomas have obstructed the flow of spermatozoa from the testis to the epididymis. **B,** The mass of spermatozoa (*right*) in the interstitial connective tissue of the epididymis is surrounded by macrophages and multinucleated giant cells. H&E stain. (**A,** Courtesy College of Veterinary Medicine, University of Illinois. **B,** Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Fig. 19-18 **Epididymitis (*Brucella ovis*), tunic adhesions, epididymis, ram.** Note the dramatic enlargement of the epididymis and the adhesion of the parietal tunica vaginalis to the visceral tunica vaginalis around the affected epididymis. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Infectious epididymitis occurs in two main ways: hematogenously by *Brucella* sp., and by ascending infection with bacteria such as *Actinobacillus seminis*, *Histophilus somni*, and *Escherichia coli*. Regardless of the causative agent, the lesion is similar and is dominated grossly and microscopically by the formation of spermatic granulomas. Microscopically, in epididymitis, the lumen has a mixture of inflammatory cells, in which neutrophils are present and macrophages are prominent, together with desquamated epithelial cells, intact and fragmented spermatozoa, and spermatozoa within multinucleate foreign-body type giant cells. If the wall of the tubule is breached, inflammation spreads to the interstitium, and macrophages become more numerous in the inflammatory exudate and collagen is deposited. Hyperplasia of the luminal epithelium of the epididymis occurs. The epithelial cells proliferate irregularly, so that thick areas of epithelium appear to enclose thin areas, leading to “intraepithelial lumen” formation. Squamous metaplasia of the epithelium is another possible outcome in chronic epididymitis. The interstitial cellular reaction is usually dominated by lymphocytes and plasma cells, and with edema and fibrosis.

1334

1335

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In rams, *Brucella ovis*, *Actinobacillus seminis*, or *Histophilus somni* infections produce a suppurative inflammatory response, with subsequent ductal epithelial hyperplasia and intraepithelial lumen formation as lesions of the early infection (Fig. 19-21) and spermatic granulomas in more chronic cases. Testicular atrophy occurs secondarily. *Brucella ovis* affects animals of breeding age, and they are often exposed during the breeding season or from other rams when not breeding. *Actinobacillus seminis* or *Histophilus somni* infect rams at puberty mostly, when hormonal alterations allow bacteria resident in the prepuce to ascend the reproductive tract, affecting the accessory genital glands first and then the epididymis.

*Brucella abortus* infection in bulls is the main infectious agent of the testis and epididymis. The disease is similar to *Brucella ovis* infection in rams, but orchitis predominates (see later discussion). The epididymis is also affected.

**Fig. 19-21 Chronic epididymitis, epididymis, ram.** Note the intertubular fibrosis and large numbers of lymphocytes and plasma cells in the interstitium. The epithelium of the duct (*top*) is hyperplastic, and the lumen contains neutrophils and spermatozoa. H&E stain. (Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

Epididymitis occurs most commonly in mature dogs. Gram-negative organisms, such as *Escherichia coli*, and presumably an ascending infection cause most cases. In acute disease, dogs suffer the effects of endotoxemia and the systemic response to infection with lethargy, fever, and a large painful and doughy scrotum. The epididymis and tunica vaginalis are usually affected, but in some cases a severe orchitis also is seen. Dogs will lick and chew at the affected scrotum and create a fistula to the scrotal contents (Fig. 19-20). Testicular degeneration is an invariable consequence of epididymitis. *Brucella canis* infection causes epididymitis also, followed by testicular degeneration and atrophy. The lesions are often unilateral and occur together with scrotal hyperemia, dermatitis, and prostatitis. The epididymis can

## Pathologic Basis of Veterinary Disease, 4th Edition

---

become greatly enlarged, especially the tail, as a result of interstitial inflammation, fibrosis, and spermatic granulomas (Fig. 19-18).

Noninfectious causes of epididymitis are exceedingly rare, and often cases that have no recoverable agent are dominated by spermatic granulomas that remain after a previous infection has been otherwise controlled.

### 19.2.2.3.6

#### Orchitis

True orchitis is much less common than epididymitis, probably because the testis is much further “upstream” than the epididymis and possibly because of the altered immunologic environment, which is antiinflammatory. Orchitis is, unfortunately, the common clinical term for inflammation of the scrotal contents. Most cases are epididymitis. Orchitis is usually accompanied by epididymitis and may be an extension of epididymitis. Primary orchitis is usually hematogenous, with examples including *Brucella abortus* in bulls, *Brucella suis* in boars, and *Corynebacterium pseudotuberculosis* in rams. It happens in several forms. Intratubular orchitis is centered on the seminiferous tubules, so it is assumed the agent and the inflammatory reaction begins there. Intratubular orchitis appears grossly as poorly defined, up to 1-cm yellow foci that become firm and white as the lesions become chronic. Initially the affected tubules have acute inflammatory debris. The lining of the tubules is lost, but the tubular outlines are present for some time. Spermatic granulomas can form any time spermatozoa make contact with extratubular tissue. In the center of these granulomas, spermatozoa can be seen free and within macrophages. Macrophages and lymphocytes infiltrate around the core of spermatozoa and macrophages and, with time, collagen is deposited at the edge of the lesion. When the lesion is predominantly in the interstitium, it is called interstitial orchitis (Fig. 19-22).

1335

1336

Necrotizing orchitis, such as is caused by *Brucella abortus* and *Brucella suis*, is the most severe form of orchitis. It is a more severe form of intratubular or interstitial orchitis, but in some cases the affected areas are so severely inflamed and the necrosis is so extensive that the original structures have formed a caseous mass. Gray-brown, initially soft and later firm, necrotic debris replaces an irregular, but large, portion of the testis. In a few extremely severe cases, a fistula develops through the scrotum. One manifestation of feline infectious peritonitis is a fibrinous and necrotic orchitis (Fig. 19-23).

Granulomatous orchitis, especially tuberculous orchitis, is now very rare as countries move toward being free of *Mycobacterium bovis*. Mycotic orchitis caused by *Blastomyces dermatitidis*, for example, occurs sporadically in endemic areas.

Inflammation of the tunica vaginalis or the epididymis can be secondary to intratubular, necrotizing, or granulomatous orchitis.

### 19.2.2.3.7

#### Neoplasia

Testicular neoplasms are common in older dogs, much less frequent in horses, and rare in other species. They usually arise from germ cells, Sertoli cells, or interstitial endocrine cells. Occasionally, neoplasms of testicular mesenchymal structures or metastatic neoplasms are found. The three common primary testicular neoplasms are seminoma, interstitial cell tumor, and Sertoli cell tumor; they occur singly or in combination. These primary neoplasms are almost always benign, and there are no features that indicate the likelihood of metastasis. Metastasis, when it does occur, is identified by nodules in the spermatic cord, scrotal lymph node, or beyond.

## Pathologic Basis of Veterinary Disease, 4th Edition

Germ cell neoplasms are seminoma, teratoma, and other less common types such as embryonal carcinoma. Seminomas are the second most common canine testicular neoplasm (Fig. 19-24, A) and the most common testicular neoplasm in the aged stallion. They are more prevalent in cryptorchid testes than in descended testes. Multicentric origin within the testis and local invasiveness are characteristic, but metastasis is rare. The neoplasm is homogenous, white or pink-gray, and firm; bulges when cut; and has fine fibrous trabeculae. Seminomas are either intratubular or diffuse, and the neoplastic cells are large, polyhedral, discretely demarcated round cells with a large nucleus, variable nuclear size, and very little cytoplasm. The mitotic rate is usually high. Giant cells, with either a single nucleus or multiple nuclei, are sometimes present (Fig. 19-24, B). Lymphoid aggregates are often present around blood vessels in seminomas and are a useful diagnostic feature.

1336

1337

**Fig. 19-22 Granulomatous interstitial orchitis, testis, ram.** There is granulomatous inflammation surrounding aggregates of spermatozoa and mineral that replaced the seminiferous tubules after they were destroyed. Fig. 19-23 **Severe fibrinous interstitial orchitis, feline infectious peritonitis (FIP), testis, cat.** Note the severe orchitis with a mixture of fibrin and plasma cells in the interstitium. the tubules are degenerate and not directly involved. The testicular lesion was the first manifestation of FIP in this cat. H&E stain. (Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

Fig. 19-24 **Seminoma, testis, dog.** **A**, Note the pale pink to beige circumscribed homogenous mass. The cut surface has a gelatinous texture and has bulged slightly on incision. The contralateral testis was atrophic. **B**, Seminomas consist of round germinal cells with a high nuclear-to-cytoplasmic ratio and frequent mitoses (*arrows*). Despite this “malignant” appearance, most are behaviorally benign. H&E stain. (**A**, Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

Teratomas arise from totipotent primordial germ cells. They are uncommon but are best known in the young horse, especially in a cryptorchid testis. The neoplasms can be large, cystic, or polycystic and can

## Pathologic Basis of Veterinary Disease, 4th Edition

---

contain recognizable hair, mucus, bone, or even teeth. Histologically, at least derivatives of two of the three embryonic germ layers (ectoderm, mesoderm, and endoderm) are present. Most teratomas have well-differentiated tissue and are benign.

Interstitial cell tumors are the most common testicular neoplasms of the dog, cat, and bull. They are readily identifiable grossly by their tan to orange color, often with hemorrhage. The neoplasm is spherical and well demarcated (Fig. 19-25, A). These neoplasms are almost always benign. They likely begin as regions of nodular hyperplasia. Some cases produce hormones, including estrogenic substances. Microscopically the cells of the bovine neoplasms vary little, but in the dog the cells can be large, round, polyhedral, or spindle shaped. The cells have abundant cytoplasm that is often finely vacuolated and often has brown pigment. The cells are arranged in solid sheets or packeted into small groups by a fine fibrovascular stroma (Fig. 19-25, B). Although hemorrhage, necrosis, and cyst formation are common, interstitial cell tumors are noninvasive and finely encapsulated.

Sertoli cell tumor is the third most common testicular neoplasm of the dog. It is rare in other species. In the dog, more than 50% of Sertoli cell tumors are located in undescended testes. The neoplasm is firm, white, and lobulated by fibrous bands and can cause enlargement of the affected testis (Fig. 19-26, A). The neoplasm can invade the spermatic cord and occasionally metastasize to the regional lymph node. Metastases beyond the regional lymph node have been reported but are rare. The neoplastic Sertoli cells either resemble normal Sertoli cells or are more pleomorphic. They can have an intratubular or a diffuse arrangement. The abundant fibrous connective tissue in Sertoli cell tumors distinguishes them from the other two common types of testicular neoplasm. Neoplastic cells tend to palisade along the fibrous stroma or form tubular structures (Fig. 19-26, B). In addition to the effects of pressure and local invasion, the other important consequence of the presence of Sertoli cell tumors is that about a third of them produce a feminizing effect, causing gynecomastia (enlargement of the mammary glands). Although some may produce estrogen, excessive inhibin secretion altering the balance between estrogen and testosterone production is thought to be responsible. A possibly life-threatening effect of hyperestrogenism is myelotoxicity, resulting in a poorly regenerative anemia, granulocytopenia, and thrombocytopenia. Other effects include alopecia, hyperplasia or squamous metaplasia of the acini of the prostate gland (Fig. 19-26, C), and adenomyosis of the epididymis. The amount of hormone produced is generally proportional to the size of the neoplasm.

Mixed germ cell–stromal neoplasms have been described in old dogs. The neoplasm-bearing testis is large and often cryptorchid. The testis is partially or completely replaced by a firm, gray-white to tan, single multilobed mass. Intimate intermingling of germ cells and Sertoli cells occurs in tubular structures of various sizes. The germ cell component extends into the surrounding tissue.

1337

1338

Fig. 19-25 **Interstitial cell tumor, testis, dog.** **A**, Note the well-demarcated, yellow-tan mass, which has bulged on incision. Such masses become hemorrhagic when they are large. Atrophy of an affected testis due to pressure is common when the tumor is large. **B**, Cells are arranged in packets surrounded by a fine fibrovascular stroma typical of endocrine cells. Their cytoplasm is pale, eosinophilic, and abundant and often has fine vacuoles. Mitoses are rare. H&E stain. ### 19.2.3 DISEASES OF THE SPERMATIC CORD

The spermatic cord and associated structures comprise the ductus deferens, pampiniform plexus, and cremaster muscle. The scrotal lymph node and the inguinal canal are related structures.

Varicocele is the local dilation of the spermatic vein in the pampiniform plexus. Older rams are most commonly affected, and the thrombosed and dilated vessels are so large that they interfere with the ability of the testis to be raised or to thermoregulate normally. This is thought to lower fertility by creating poor spermatozoal motility, immature spermatozoa in the semen, and testicular degeneration. The dilation in the venous plexus is located near the inguinal ring and does not involve the complex distal part of the pampiniform plexus ([Fig. 19-27](#)). About half the cases are bilateral, and the unilateral cases are evenly divided between the left and right side. Thrombosis of affected vessels is common.

1338

1339

Fig. 19-26 **Sertoli cell tumor, testis, dog.** **A**, Sertoli cell tumors are firm, white, and often lobulated, and the lobules are surrounded by fibrous bands. **B**, Histologically, Sertoli cell tumors have tubular structures lined by cells that resemble Sertoli cells and are surrounded by septa of fibrous tissue. H&E stain. **C**, Prostate, squamous metaplasia. Functional Sertoli cell tumors that secrete estrogen can induce hyperplasia and/or squamous metaplasia of the prostate gland. Normal epithelium of the prostatic ducts (transitional) and glandular acini (columnar) is replaced by stratified squamous keratinizing epithelium. H&E stain. (**A**, Courtesy Dr. K. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Torsion of the spermatic cord is seen in undescended testes, especially when there is a testicular neoplasm present. Torsion also occurs periodically in the stallion and is a cause of colic. Torsion causes venous occlusion with a resultant venous infarction of the testis especially and also of the epididymis.

Inflammation of the spermatic cord (funisitis, scirrhus cord) occurs after the contamination of a castration wound. Sometimes the lesion is acute and necrotizing, but more often it is chronic and a scirrhus cord is encountered. Great enlargement of the distal part of the cord is due to exuberant granulation tissue in which numerous small pockets of pus are scattered. Staphylococci are the organisms frequently recovered from the pus in the horse. The term “botryomycosis” has been used for these staphylococcal pyogranulomas. Radiating club-shaped eosinophilic deposits (Splendore-Hoeppli reaction) are present around the central clusters of bacteria.

Inguinal hernia and lymphadenopathy of the scrotal lymph nodes are a differential diagnosis for masses or swellings in the region of the spermatic cords. Older rams and stallions are particularly prone to inguinal hernia, which is a cause of scrotal enlargement and colic in stallions. Caseous lymphadenitis in rams and lymphoma in dogs are a cause of scrotal lymphadenopathy.

**Fig. 19-27 Varicocele, pampiniform plexus, ram.** This extremely large varicocele (*arrows*) is larger than the testis. It is multinodular from large thromboses filling the dilated veins. (Courtesy Dr. P. W. Ladds, James Cook University of North Queensland.)

### 19.2.4 DISEASES OF THE ACCESSORY GENITAL GLANDS

The accessory genital glands include the ampullae, vesicular glands, prostate, and bulbourethral glands. The ampullae and vesicular glands are derived from the mesonephric duct, and the prostate and bulbourethral glands are derived from the urogenital sinus. Their hidden location within the pelvic canal means that they are often neglected in examination of the reproductive tract.

#### 19.2.4.1 AMPULLAE

There are very few diseases of the ampullae, and the majority are microscopic. Bulls have variation in the patterns of insertion of ampullae at the seminal colliculus. They can be above and below the vesicular glands. The membrane between the ampullae is the location for the remnants of the paramesonephric duct—the cystic uterus masculinus—in rams and bulls. Hyperestrogenism can cause these to become greatly enlarged.

Ampullitis is a feature of infection with agents that cause epididymitis and vesicular adenitis, including but not restricted to *Brucella abortus*, *Brucella ovis*, *Actinobacillus seminis*, *Histophilus somni*, and many other agents. It may precede epididymitis as part of an ascending infection or occur when organisms and inflammatory products descend into the ductus from an inflamed epididymis.

#### 19.2.4.2 VESICULAR GLANDS

The major disease of the vesicular glands (seminal vesicles) is inflammation of the gland, and often it is clinically silent, except in the bull. Vesicular adenitis (seminal vesiculitis) is a significant disease in the bull because it reduces fertility, particularly in young bulls. Inflammation in the vesicular glands contributes inflammatory cells and mediators to the semen, thus reducing the ability of spermatozoan to survive freezing. Young bulls, in their first breeding season, are especially affected. The cause is most likely infectious; various organisms including viruses, protozoa, *Chlamydia*, *Ureaplasma*, *Mycoplasma*, *Brucella abortus*, and other bacteria having been investigated over the years. The pathogenesis is uncertain, but hypotheses include ascending infection, descending infection, hematogenous spread, congenital malformation preventing excretion of fluid and spermatozoa, and reflux of spermatozoa or urine into the glands.

The common form of vesicular adenitis is a chronic interstitial inflammation (Fig. 19-28, A and B). In some cases, the glands are enlarged and firm and have loss of lobulation. Collagen is deposited between the acini. Lymphocytes, plasma cells, macrophages, and a few neutrophils and eosinophils are present in the interstitium. The lumens have neutrophils, desquamated epithelial cells, and debris (Fig. 19-28, B). Metaplasia of glandular epithelium to a stratified squamous type is common. In some bulls, much disorganization and denuding involve the epithelium of inflamed vesicular glands.

Fig. 19-28 **Chronic vesicular adenitis, vesicular gland, cut surface, ram.**

**A**, The normal lobulation of the vesicular gland is distorted by fibrous tissue that surrounds the glandular tissue. **B**, Chronic vesicular adenitis (*Brucella ovis*) (different than Fig. 19-28, A). Glandular acini are filled with degenerating neutrophils and debris, and neutrophils are migrating through the acinar epithelium. The interstitium is heavily infiltrated by plasma cells and lymphocytes. H&E stain. (**A** and **B**, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph.)

Vesicular adenitis can be part of the range of lesions caused by *Burkholderia pseudomallei* in boars and the many *Brucella* species, especially *Brucella ovis* in sheep. Vesicular adenitis is occasionally seen in stallions.

### 19.2.4.3

#### PROSTATE GLAND

The prostate gland is derived from the urogenital sinus. Both estrogens and androgens have trophic action on the prostate gland.

The only animal with any frequency of prostatic disease is the dog. There are three main diseases and their prevalence is, in order, hyperplasia, neoplasia, and prostatitis.

Prostatic hyperplasia is a common age- and testosterone-dependent condition. The dog is the only domestic animal species that spontaneously develops prostatic hyperplasia with age (Fig. 19-29, A and B). Clinical consequences of prostatic hypertrophy include constipation from the “ball valve” effect of a large prostate forced into the pelvis during attempted defecation. Although obstruction of the urethra is a feature of prostatic hyperplasia in humans, stenosis of the urethra only occasionally occurs in the canine disease. Enlargement of the prostate is hormone related, but the precise mechanisms are unknown. Hypertrophy of the gland does not occur in castrated dogs, and removal of androgens by castration of affected dogs is therapeutic. Administration of estrogens causes enlargement of the gland. Acinar hyperplasia possibly is caused by androgen excess (Fig. 19-29, C), and fibromuscular hyperplasia is caused by estrogen excess, but the contribution of these two elements to the enlargement of the gland can overlap considerably. Enlargement of the gland is usually uniform. On occasion the hyperplasia is cystic, and in extreme cases, a large single cyst or multiple small cysts are found. Microscopically, there is hyperplasia of the acinar

## Pathologic Basis of Veterinary Disease, 4th Edition

epithelium and hyperplasia of the interlobular and to a lesser extent the intralobular fibromuscular stroma. Some acini are distended with fluid and have a flattened epithelium.

Estrogen-induced hypertrophy of the canine prostate gland, most often because of the presence of Sertoli cell tumor, has the added feature of squamous metaplasia of acinar epithelium, ducts, prostatic urethra, and uterus masculinus (Fig. 19-26, C). Flattened keratinized epithelial cells are desquamated into the acini, and neutrophils and other inflammatory cells are present. Squamous metaplasia of the prostate gland in dogs is not preneoplastic.

Prostatic and paraprostatic cysts occur periodically in dogs, and their origin has been debated for years. Some may be an enlarged cystic uterus masculinus (see cysts of the reproductive tract), but many are likely to be hyperplastic cysts formed when cystic acini extrude through the incomplete muscular layer of the prostatic capsule, in a manner similar to adenomyosis of the uterus. Paraprostatic cysts can attain giant proportions, as large as 30 cm in diameter. Some become infected and abscessed.

1340

1341

**Fig. 19-29 Prostatic hyperplasia, prostate, dog.** **A**, Prostates of two dogs of different ages (*oldest on the right*). Both prostates are bilaterally and symmetrically larger than normal pubertal prostates. **B**, The lighter white tissues that in some areas bulge from the cut surface are areas of hyperplasia. A hyperplastic prostate is symmetrically enlarged and detectable on rectal palpation, ultrasonography, or by gross examination at necropsy. **C**, The prostatic acini are larger than normal, as the epithelium is hyperplastic and the cells enlarged (hypertrophy). Note the abundant granular apical cytoplasm and the uniform size and shape of the cells. mitotic activity is very low. H&E stain. (**A**, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph. **B**, Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C**, Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Carcinoma of the prostate in the dog is the only prostatic neoplasm of any importance in domestic animals (Fig. 19-30, A). A similar disease is exceedingly rare in the cat. The cause, possibly related to an abnormal hormonal environment, has not been well defined. Prostatic hyperplasia appears not to precede neoplasia, although the two lesions are found together in intact dogs. Some of the clinical signs of carcinoma of the prostate are similar to those of prostatic hyperplasia because of the enlargement of the organ. Carcinoma and its metastases cause cachexia and locomotor abnormalities through pressure and invasion of nearby structures, including bones. Grossly, there are two general appearances. The most obvious is the type that causes increased firmness, asymmetric enlargement (Fig. 19-30, B), partial or complete loss of the median raphe, and cystic cavities in the prostate gland. The prostate gland becomes large and attached to other pelvic structures. The second type is mostly periurethral, with a necrotic and cystic cavity within the prostatic capsule. It causes minimal enlargement of the gland, but urinary obstruction and metastatic disease are present. Castrated dogs are usually affected.

Much has been written and said about the prevalence of different types of neoplasia of the prostate. Some authors have divided them into adenocarcinoma and transitional cell carcinoma; the latter presumably arise from the pelvic urethra or from prostatic ducts. This is perhaps too simplistic, as there is also an intermediate category of mixed glandular and transitional types. A detailed study of the cellular origins of carcinomas was unsuccessful as there are no specific markers to separate those derived from acinar or urothelial tissue. This is possibly because of a common origin of prostatic ducts and glands, and for urothelium in general. Because of this, we choose to use the term “carcinoma of the prostate” as a general term and to refer to adenocarcinoma, mixed carcinoma, squamous cell carcinoma, and transitional cell carcinoma when the histologic type is purely glandular, mixed squamous, or urothelial.

1341

1342

**Fig. 19-30 Carcinoma, prostate, dog.** **A**, The pelvic tissues of this dog contain many coalescing nodules of metastatic carcinoma that have spread from the prostate, which is barely recognizable beneath the bladder (*opened, upper*). Prostatic carcinomas are usually asymmetric and lobulated white-to-gray masses that expand the size of the gland and may compress the urethra (dysuria) and the colon (difficulty defecating, ribbon stools). **B**, Cross section. Note the asymmetric enlargement. The focal white areas are regions of necrosis within a gland that is enlarged by neoplastic epithelial cells that induce the abundant fibrous tissue that is also present. **C**, Note the anaplastic prostatic epithelial cells arranged in acini and solid lobules. There also may be stromal or lymphatic invasion and desmoplasia (scirrhous response). H&E stain. (**A**, Courtesy Dr. M. Howard, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. J. A. Ramos-Vara, College of Veterinary Medicine, Michigan State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **C**, Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Microscopically, prostatic intraepithelial neoplasia, described as a precursor of human prostatic cancer, has been recognized in the dog, but only in conjunction with concurrent carcinoma of the prostate. The features are disruption of basal cell layer, increased mitotic index, and increased density of small blood vessels. The appearance of a carcinoma reflects attempted differentiation toward glandular, urothelial, or epidermal tissues, or mixtures of two or more (Fig. 19-30, C). There are varying degrees of stroma between the neoplastic epithelial cells. Some mixed neoplasms also contain sarcomatous tissue. In dogs, no specific regions of the prostate have a predilection for the development of hyperplasia or neoplasia.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The prognosis for carcinoma of the prostate is generally poor. About 40% are in sexually intact dogs, 80% of affected dogs have metastases to a lymph node and/or lung at the time of diagnosis, and 20% of these have metastasized to bone.

Prostatitis is seen periodically and can be clinically significant if toxemia accompanies the infection or if the gland becomes large enough to cause urinary obstruction. In the dog, prostatitis can be found in old animals, often together with hyperplasia, or in young animals without hyperplasia. Although increased concentrations of zinc in prostatic fluid are associated with antimicrobial properties in men and dogs, resistance to infection and resolution of infection are not correlated with zinc concentrations in prostatic tissue in the dog. Prostatitis can usefully be divided into acute, chronic, abscess formation, and specific (*Brucella canis*) forms. Organisms such as *Escherichia coli*, *Proteus vulgaris*, and others invade from the urethra. The affected organ can be diffusely or focally involved, swollen, congested, and edematous (Fig. 19-31, A). The early microscopic lesion is catarrhal to purulent inflammation of the acini, expanding later to involve the interstitium, with abscess formation (Fig. 19-31, B). The abscesses can persist or be replaced by fibrous tissue. Prostatitis is part of the spectrum of lesions caused by *Brucella canis* in the dog, and the prostate can be the site of persistence of the organism. A subacute interstitial inflammation causes enlargement and fibrosis of some lobules (Fig. 19-31, C). Dogs have a common, clinically insignificant, chronic prostatitis of unknown cause.

19.2.4.3.1

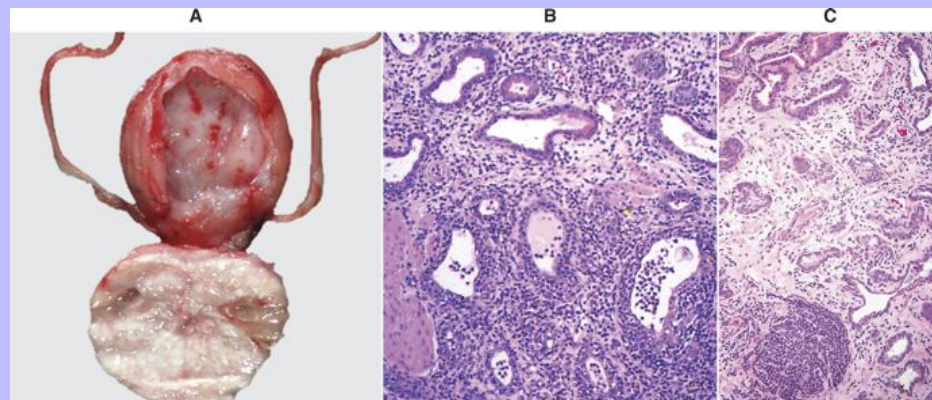

### Bulbourethral Glands

The bulbourethral gland, as with the prostate, is derived from the urogenital sinus. There are few lesions of the bulbourethral glands, no doubt because of their dense structure and lack of lumina to allow bacterial growth and persistence. The major disease of this gland is seen in castrated male sheep grazing clover pasture with a high estrogen content. The glands of these wethers have hypertrophy, squamous metaplasia, and cyst formation that can be massive and cause perineal swellings.

1342

1343

Fig. 19-31 **Prostatitis, prostate, dog.** **A**, Acute prostatitis, cut surface. The prostate is enlarged with edema, and there are myriad white foci of inflammatory cells instead of the usually smooth red surface. Clinically, this condition is usually painful. **B**, Acute prostatitis. Note that the glands and interstitium contain large numbers of neutrophils. Most of these infections are of bacterial origin and develop after bacteria ascend the urethra. H&E stain. **C**, Chronic prostatitis. Note that the glands and interstitium contain large numbers of lymphocytes and macrophages and a large lymphoid nodule (*bottom*). Follicular lymphoid hyperplasia is a common finding in chronically infected tissue. The abundant interstitial stromal is from fibroplasia and chronic inflammation. Most cases of chronic prostatitis have a bacterial origin. H&E stain. (**A**, **B**, and **C**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

### 19.2.5 DISEASES OF THE PENIS AND PREPUCE

Disease of the penis and prepuce is relatively rare, yet infection is common and extremely important for food-producing animals. Many of the venereally transmitted diseases, such as trichomoniasis, campylobacteriosis, herpesviruses, and papillomaviruses, are present in the prepuce and do not cause severe disease or have a mild and self-limiting course. The penis is protected from trauma and drying by the prepuce, and this very environment is permissive of many infectious diseases. Some induce an immune reaction and or inflammation.

Phimosis is the inability to extrude the penis, and paraphimosis is the inability to retract the penis into the prepuce.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 19.2.5.1 DEVELOPMENTAL ABNORMALITIES

Persistent frenulum is a relatively common and minor anatomic abnormality rather than a serious defect, but it can have an important deleterious effect in limiting the extent to which the penis can be protruded from the sheath and in causing the erect penis to be curved instead of straight (Fig. 19-32). Persistent frenulum is of importance in bulls and boars. Judging by the frequent occurrence of large flaps and tags of tissue on the ventral raphe of the penis, transitory persistence of the frenulum is quite common. The raphe of the penis and prepuce are remnants of the frenulum, a thin membrane ventral to the penis that normally ruptures at puberty, probably as the result of simple mechanical forces. Persistent segments of frenulum are well vascularized, usually occur at the distal end of the penis, and can connect the penis to the prepuce or the penis to itself.

The penis is subject to many abnormalities of size and form, such as congenital absence, hypoplasia, duplication, directional deviations, and, in ruminants, absence of the sigmoid flexure and abnormal locations of the insertions of the retractor muscles. None of these lesions is common.

Hypospadias and epispadias are malformations of the urethral canal that create abnormal openings of the urethra on the ventral surface of the penis (hypospadias) or on the dorsal surface (epispadias). In hypospadias, the urinary opening is anywhere from the glans to the penile shaft, penoscrotal junction, or the perineum. Their importance is in the potential for causing urinary obstruction and in interference with normal insemination.

1343

1344

**Fig. 19-32 Persistent frenulum, penis, bull.** A tag of tissue (forceps) connecting the penis and prepuce has caused the penis to be curved ventrally, thus making intromission impossible. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 19.2.5.2 HEMORRHAGE AND PENILE HEMATOMA

The penis is a highly vascular structure, and the presence of erectile tissue and high pressures during erection and coitus make the potential for severe or even fatal hemorrhage high. Trauma to the penis is usually responsible; cuts, lacerations, and surgical incisions bleed profusely. This is particularly evident with penile hematoma (penile deviation; broken penis) in bulls. A similar disease in the ram is reported. During mating, the penis of the bull probes for the vulva, and when appropriate, the copulatory thrust and ejaculation is done with great force. If the penis deviates from its intended target, tremendous pressure is applied to the region of the sigmoid flexure and insertion of the retractor penis muscles, resulting in rupture and hemorrhage (Fig. 19-33). Hematomas develop just cranial to the scrotum. Small hematomas heal without complications, but depending on the extent of the injury and hematoma, granulation and scar tissue is formed and prevents extension (phimosis) of the penis. In severe cases, hemorrhagic shock can occur. Some hematomas become infected and result in a penile abscess.

### 19.2.5.3 INFLAMMATION

Inflammation of the penis is phallitis, of the glans penis is balanitis, and of the prepuce is posthitis. Inflammation of the penis and prepuce (phaloposthitis or balanoposthitis) occurs mostly in castrated animals. This could be the result of alterations to structure because of a lack of testosterone and/or normal development and the tendency of these animals to urinate within their prepuce. Retention of urine in the preputial cavity creates an environment for the overgrowth of bacteria. Those that produce urease split urea to ammonia, a toxic molecule that damages the preputial epithelium, causing erosion and ulceration.

**Fig. 19-33 Penile hematoma, penis, bull.** **A**, The large hemorrhage around the penis at the sigmoid flexure is a hematoma from rupture of the penis during forced deviation. Illustrated is the site of rupture of the penis with a blood clot filling the rupture site. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Ovine posthitis (pizzle rot) is a disease of wethers mostly and is caused by urease-producing *Corynebacterium renale*. When the urine has a high concentration of urea, *Corynebacterium renale* produces ulceration of the prepuce near the orifice. A high-protein diet predisposes to the disease. Lack of testosterone is also involved because the disease can be prevented by administration of androgens to wethers. If the preputial orifice becomes blocked by swelling, the disease becomes much more severe, spreading beyond the initial small ulcer on the hairless skin of the prepuce to diffusely involve the mucosa, with ulceration of the glans penis and loss of the urethral process. Scarring and phimosis can result. In severe cases, the preputial orifice becomes blocked and the animals die from urinary retention.

1344

1345

Nonspecific posthitis occurs in all species and, in the gelding, is believed to occur because of a lack of extrusion of the penis with a resultant buildup of the waxy smegma and bacterial overgrowth. A foul-smelling prepuce and posthitis is the result. Dogs commonly develop a nonspecific and purulent discharge of the prepuce. Foreign material sometimes is found in the prepuce; bulls, rams, and bucks can have matted hair around their penis to form a constricting ring (colloquially called “hair ring”). This can cause a posthitis or even avascular penile necrosis. It is assumed the deposition of hair in this location is because of homosexual activity, and the rubbing of the penis on the posterior of other animals. Dogs, especially those of the chondrodystrophic breeds with short legs, will impact the prepuce with sand.

All species can have traumatic wounds of a variety of types and severity, resulting from mating injuries. Mating or attempting to mate through fences can cause lacerations of varying severities. Owners attempting to “untie” mating dogs can cause degloving injuries to the penis. Horses with penile laceration can develop exuberant granulation tissue (“proud flesh”) of the penis.

Trauma is part of the pathogenesis of preputial prolapse in bulls. Bulls of *Bos indicus* type have a pendulous sheath that is easily lacerated by sticks or other sharp objects. Temporary eversion of the prepuce is common in these and other bulls and is related to inadequate muscular control. The everted preputial mucosa is subject to injury and to edema and inflammation. The prepuce remains everted (prolapsed), swells, dries, and is further lacerated, leading to a cycle of injury and inflammation that are permanent.

Preputial diverticulitis in boars is unique to this species because they are the only domesticated animal to have this anatomic structure normally. The pathogenesis is not completely known, but deflection of the penis into the normal preputial diverticulum of the boar because of malformation or masturbation will predispose this diverticulum to local infection. The diverticulum is also a location for papillomas to develop.

Herpesviruses can cause a multifocal phalloposthitis in several species. Bovine herpesvirus 1 causes a phalloposthitis in the bull, progressing over the course of a few days from hyperemia and swelling to vesicles and pustules and then 1- to 2-mm ulcers, especially of the glans penis (Fig. 19-34). In the vesiculopustular stage, intranuclear inclusion bodies are present briefly in epithelial cells of the penis and prepuce. Ulcerative balanoposthitis with acidophilic intranuclear inclusions has been observed in goats and is considered a result of caprine herpesvirus infection. Equine herpesvirus 3 is the cause of equine coital exanthema, a disease of stallions and mares with a similarly short clinical course, but with larger (15 mm) ulcers with a predilection for the body rather than the glans of the penis. Canine herpesvirus reportedly causes inflammation at the base of the penis and the reflection of the prepuce but does not cause the formation of pustules or ulcers. Resolution of these lesions in the affected species is rapid, leaving only hyperplastic mucosal lymphoid nodules and small areas of depigmented mucosa. Bovine herpesvirus 1, suid herpesvirus 1 (pseudorabies virus) in pigs, caprine herpesvirus 1, and canine herpesvirus can persist in a latent state, capable of becoming reactivated by stress or treatment with corticosteroids.

**Fig. 19-34 Phaloposthitis, bovine herpesvirus 1, penis (free part), bull.**  
Note the vesicles and pustules. Bovine herpesvirus 1 causes hyperemia, swelling, vesicles, pustules, and 1- to 2-mm ulcers, especially of the glans penis. Intranuclear inclusion bodies are present microscopically, briefly in epithelial cells of the penis and prepuce during the vesiculopustular stage. (Courtesy Dr. K. McEntee, Reproductive Pathology Collection, University of Illinois; and Dr. J. King, College of Veterinary Medicine, Cornell University.)

Papillomaviruses affect the penis of many species. Typical “warts” are produced in the dog, sarcoids are seen in horses, and the bull develops fibropapilloma (Fig. 19-35, A and B). The bovine disease is discussed in the section on penile neoplasia.

Other organisms are capable of causing phaloposthitis. These include *Strongyloides papillosus* in the bull and the larvae of *Habronema* spp. in the horse. In equine habronemiasis, the gross lesion has the same elevated nodular bleeding surface as granulation tissue or a sarcoid. Microscopically, however, the lesions are distinct tracks of larval migration filled with debris and surrounded by fibrovascular tissue rich in eosinophils. The well-known bovine venereally transmitted diseases of campylobacteriosis and trichomoniasis cause no lesions or minimal nonspecific lesions of the penis and prepuce, even though they reside there.

Obstruction of the penile urethra, especially the urethral process of small ruminants, is common with urolithiasis. The narrowest part of the urethra is the urethral process, and small uroliths that pass through the rest of the urethra become lodged near the tip. Depending on the degree of obstruction, necrosis, and rupture, penile and preputial necrosis can occur. Many animals die of bladder rupture before necrosis of the urethral process or penis occurs.

1345

1346

Fig. 19-35 **Penile fibropapilloma, glans penis, bull.** **A**, There is a large exophytic papillary mass protruding from the penile epithelium. This large proliferative lesion on the penis is typical of a fibropapilloma. **B**, Note the abundant connective tissue covered by hyperplastic stratified squamous epithelium that is thickened and has elongated epidermal-dermal interdigitations that penetrate deeply into the connective tissue. ### 19.2.5.4 NEOPLASMS

Primary neoplasms of the penis and prepuce are mostly restricted to a limited number of types and species. Metastatic or multicentric neoplasms affect these tissues rarely.

## Pathologic Basis of Veterinary Disease, 4th Edition

Transmissible venereal tumor (TVT) of the dog is the only naturally transmitted neoplasm of any species, as it is a type of xenotransplantation. TVT is a round cell neoplasm. The primary neoplasm is usually on the external genitalia, but extragenital primaries and metastatic neoplasms also occur. In the male dog, the neoplasm is found on the penis, more often on the proximal parts, and not often on the prepuce (Fig. 19-36, A). The neoplasm can be single or multiple, a few millimeters to 10 cm in diameter, with an inflamed, ulcerated, cauliflower-like surface. Microscopically the neoplasm is the same as it is in the bitch, composed of sheets of round cells and minimal stroma. The neoplastic cells are large and uniform, with a large nucleus and nucleolus, distinct cell outline, and numerous mitotic figures (Fig. 19-36, B). Regression and recovery are the rule. The cells express major histocompatibility complex class II antigen, and there is infiltration of inflammatory cells, including increased numbers of T lymphocytes during the regression of the neoplasm. Based on data obtained from immunologic, cytogenetic, and nucleotide sequence studies, the neoplasm is thought to arise from a specific genetic alteration of canine histiocytes, followed by the transmission of abnormal cells from dog to dog.

**Fig. 19-36 Transmissible venereal tumor, penis, dog. A,** There is a large multinodular mass involving the penis and the prepuce at its reflection from the penis. **B,** Neoplastic cells are round, uniform in size, and often divided into packets by a fine fibrous stroma. Mitoses are frequent (*arrows*). H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. M. J. Abdy, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Squamous cell carcinoma of the penis is of importance in the horse and to a lesser extent in the dog. In the horse, both stallions and geldings have neoplasms, and the common site is the glans penis (Fig. 19-37, A).

## Pathologic Basis of Veterinary Disease, 4th Edition

Although proliferative masses do occur, the usual growth habit is one of infiltration with sclerosis, which results in an enlarged penis that is focally necrotic and ulcerated. Microscopically the neoplasm is well differentiated, with well-developed keratin pearls (Fig. 19-37, *B*). Metastasis to the superficial inguinal (scrotal), deep inguinal, and medial iliac lymph nodes can occur. The sheath becomes edematous because of lymphatic obstruction, and the preputial cavity becomes distended by retained smegma, inflammatory debris, and urine.

1346

1347

**Fig. 19-37 Squamous cell carcinoma, penis, horse (gelding).** **A**, A very large ulcerated mass protrudes from the glans penis. The urethral opening is visible (*arrow*). **B**, Neoplastic squamous epithelial cells are often arranged around “keratin pearls.” Mitoses are frequent (*arrows*). H&E stain. (**A**, Courtesy Dr. R. A. Foster, Ontario Veterinary College, University of Guelph. **B**, Courtesy Dr. M. J. Abdy, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Papilloma (or fibropapilloma) occurs on the glans penis of young bulls (Fig. 19-35, *A and B*). It is attributable to bovine papillomavirus type 1 infection, but the exact pathogenesis has not been elucidated. The papillomaviral origin is expected, as affected animals are young, usually in their first breeding season, and the lesions are self-limiting. They are histologically typical of fibropapillomas elsewhere, including the occasional observation of intranuclear inclusion bodies. The single or multiple warty growths have a significant fibrous core and a papilliferous epithelial covering. The proportions of epithelial and fibrous tissue vary greatly from case to case. Surface ulceration is often extensive following spontaneous necrosis

## Pathologic Basis of Veterinary Disease, 4th Edition

---

or trauma. Larger neoplasms can interfere with breeding by causing pain or by their physical size. Affected bulls can develop an aversion to mating. The disease is usually self-limiting.

## 20 Chapter 20 Eye, Eyelids, Conjunctiva, and Orbit\*

BRIAN P. WILCOCK

### 20.1 INTRODUCTION

Because of its superficial anatomic location and the transparency of its anterior pole, the globe is the only organ that can be directly examined in great detail by the clinician. As a result, the evaluation of the gross lesions of the eye is really the realm of the clinical practitioner and especially the clinical ophthalmologist. The terminology of ophthalmic pathology is identical to the terminology of clinical ophthalmology, which unfortunately is complex and seemingly designed to intimidate anyone other than the most determined.

Examining a globe is really a miniature postmortem in itself. The embryologic development, general reactions to injury, and specific diseases are as different among the cornea, uvea, and retina as they are among the lung, liver, and kidney. Therefore it is traditional to consider the diseases of the eye as a series of relatively separate topics defined by the anatomic portion of the eye under consideration. There are certainly some diseases affecting the eye as a whole, but they are actually in the minority.

All adult mammalian globes have similar general anatomy, depicted in [Fig. 20-1](#). The globe is a spherical biologic camera with an elaborate autofocus lens derived from surface ectoderm and a light-absorbing film plate (retina) created by an outgrowth of specialized neurons from the brain. All other structures within and surrounding the globe are simply there to ensure the optimal function of the cornea, lens, and retina.

The eye develops as a tentacle of brain tissue that reaches out to just under the skin surface of the developing embryo. The eye's purpose is to gather sensory information in the form of photons of light, which are absorbed by neurons specifically adapted to convert light into electrical energy. To facilitate access by those photons to the light-sensitive neurons of the retina, the surface ectoderm, which would normally form ordinary skin, undergoes specialized differentiation into the cornea and lens as the tentacle of the brain comes into proximity with it. Details of embryogenesis will be discussed in later sections of this chapter.

The details of ocular anatomy can be found in any histology text, but there are some specific features that are particularly relevant to ocular pathology. A few of the most important features are emphasized here:

1. The globe is a sealed, fluid-filled sphere, which is protected from noxious influences by a bony orbit, mobile eyelids, a thick fibrous outer shell of cornea and sclera, and a series of vascular and epithelial tight junctions within the uvea and retina referred to as the blood-eye barrier.
2. Although the anatomy and physiology of the globe serve to protect it from many injuries affecting other parts of the body, the same unique features make it extremely susceptible to the propagation of injury once those defenses have been overcome. The fluid media within the globe allows diffusion of infectious agents and chemical mediators of inflammation throughout the globe. The same defenses that prevent entry of various types of chemical or biologic agents also prevent drainage of dangerous by-products of tissue injury and inflammation.
3. Proper visual function requires that very precise anatomic relationships be maintained among the constituent parts of the globe. Minor changes in those relationships that would be insignificant in most other tissues can have devastating results within the globe. Common examples include blindness resulting from minor accumulations of serous exudate behind the retina (serous retinal detachment), or

1349

1350

## Pathologic Basis of Veterinary Disease, 4th Edition

accumulation of edema fluid within the cornea that significantly alters corneal clarity even to the point of blindness. Many of the critical tissues within the globe are unforgiving even of minor changes associated with inflammation or wound healing that, in most other tissue, would be regarded as insignificant.

4. Most of the visually critical tissues within the globe have negligible regenerative capacity. Some, like the adult retina, are essentially postmitotic and cannot regenerate at all. Others, such as the lens and cornea, are capable of limited regeneration, but the regeneration never recreates a perfect structural or functional replica of the original tissue. Many of the most significant intraocular lesions are related to events of wound healing (epithelial proliferation, angiogenesis, and fibrosis), which are desirable events in most tissue but cause serious functional impairments in the globe.
5. Unlike most other tissue, the eye has essentially no reserve capacity. In many tissues we struggle to determine whether a lesion is or is not “functionally significant.” There is probably no such thing as a functionally insignificant lesion within the globe. Every single focus of necrosis, inflammation, or scarring probably has a visual consequence even if the degree of impairment is not easily measured.
6. Vision requires that the cornea, lens, and fluid media within the globe remain optically clear. This means that accumulation of exudates, or changes in refractive properties related to conditions such as edema and fibrosis, are extremely damaging even though these reactions to injury may be beneficial to the survival of the globe itself. There is not much point in having a globe that has survived, but has forfeited vision.
7. Ocular bystander injury occurs when injury to one component of the globe “spills over” and affects other parts of the globe. Examples include the following:
  - Inflammatory effusion from choroiditis, which can cause retinal detachment
  - Alteration in aqueous composition and flow, which can lead to cataracts
  - Organization of intraocular exudates, which can cause tractional retinal detachment or glaucoma secondary to pupillary block or peripheral anterior synechia
  - Chemical mediators of wound healing in chronic uveitis that stimulate preiridal fibrovascular membranes and corneal stromal vascularization

**Fig. 20-1** Schematic diagram of the anatomy of the eye. (*Modified from Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders; and Slatter D: Fundamentals of veterinary ophthalmology, ed 3, Philadelphia, 2001, Saunders.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 20.1.1 STRUCTURE AND FUNCTION

#### 20.1.1.1 CORNEA

The cornea is the anterior third of the fibrous tunic that provides structural support for the retinal and uvea. It is a three-layered sandwich about 1 mm thick. It has a thick center of densely compacted collagen fibrils covered on its anterior surface by stratified squamous epithelium derived from fetal surface ectoderm. On its inner (posterior) surface, it is covered by a single layer of cuboidal epithelial cells, known as the corneal endothelium, which is derived from periocular mesenchyme (Fig. 20-2). The corneal epithelium is 6 to 10 cells thick and has a turnover time of 5 to 7 days. The adult corneal endothelium of most domestic mammals does not replicate.

1350

1351

**Fig. 20-2 Normal cornea, dog. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)**

The cornea is an adaptation of skin. These adaptations to the epidermis are designed specifically to render it transparent. The surface epithelium differs from that of skin in that there is no keratinization, pigmentation, hair follicles, or adnexal glands. The corneal stroma resembles dermis, except that it lacks blood vessels, hair follicles, and leukocytes. It has relatively few fibroblast-like cells (keratocytes) and a highly regimented organization of its collagen fibrils. These fibrils are arranged in compact lamellae with a space between them that matches the wavelength of visible light. Thus the cornea allows the passage of light without any scattering. To further facilitate the unimpaired passage of light, the corneal stroma is maintained in a dehydrated state compared with that of most other tissue. That dehydrated state is maintained passively by intercellular junctions within the corneal epithelium and endothelium, which exclude water from the tear film and anterior chamber, respectively. It is further maintained by the active removal of electrolytes (and thus water) by energy-dependent membrane pumps within the corneal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

endothelium and to a much lesser degree the overlying epithelium. The avascular cornea is permitted to exist in this highly privileged anatomic and physiologic state only as long as its “support system” is working properly. It must be protected from desiccation and irritation by properly functioning eyelids and lacrimal secretion, nourished by a tear film that is biochemically normal and delivered in adequate amounts, and replenished by germinal cells resident in the adjacent conjunctiva and sclera. The failure of any of these support systems results in corneal decompensation, seen clinically either as necrosis or as reversion of the cornea to a skinlike state, which although much more durable is unfortunately also opaque.

20.1.1.2

### UVEA

The uvea is the nourishing vascular tunic of the globe. It is made up of the iris, ciliary body, and choroid. It includes the pigmented stroma and muscles of the iris and ciliary body, and the light-reflecting mirror known as the tapetum, which is buried within the dorsal choroid of all domestic species except the pig. It borders the fluid-filled cavities of the globe: the anterior chamber, posterior chamber, and vitreous. The uvea is surrounded exteriorly by the sclera.

The uvea is formed in part by neurectoderm from the primary optic vesicle, and in part by periocular mesenchyme. Its primary function is to provide nutrients to the avascular lens and to the outer half of the retina. In its general structure, it is similar to the lamina propria of the various tubular organs, such as the intestine or reproductive tract. It is rich in fibrous tissue, nerves, blood vessels, and melanocytes. In contrast to the lamina propria of other tissue, however, it contains virtually no resident lymphocytes or plasma cells. Although the vasculature of the uvea is in free communication with systemic vasculature, access by infectious agents or tumor cells from the blood into the globe via the uvea is normally prevented by a series of strategically located tight junctions, which are collectively referred to as the blood-eye barrier (see later discussion under Defense Mechanisms).

20.1.1.3

### LENS

The lens is a biconvex, avascular, transparent accumulation of elongated epithelial cells, suspended within the pupillary aperture. Its shape and elasticity vary greatly by species and with age. It is surrounded by the lens capsule, which is a thick basement membrane (predominantly type IV collagen) produced throughout life by the lens epithelium. That germinal epithelium forms a single layer of cuboidal epithelial cells just below the capsule along the anterior surface of the lens. The epithelium is absent from the posterior surface of the lens. Near the equator of the lens, these epithelial cells migrate inwardly and elongate to become lens fibers. As they elongate, the cells also lose most of their cytoplasmic organelles and eventually lose their nuclei. They develop complex “ball and socket” interdigitations of their plasma membranes and many gap junctions that allow each lens fiber to adhere tightly to all of its adjacent fibers.

New lens fibers are recruited from the germinal cells of the lens epithelium throughout life, so the lens continues to grow. Its net growth is partially counterbalanced by a progressive increase in the density of the center of the lens (the lens nucleus), which is formed by the oldest lens fibers. Gradually the increasing number of aged fibers within the progressively expanding lens nucleus makes the lens less transparent (so-called nuclear sclerosis) and less flexible, so that at least in some species, there is a loss of focusing ability (accommodation) with age.

1351

1352

The purpose of the lens is to further refract light that has passed through the cornea and to focus that light onto the retina. To accomplish this, the lens obviously must remain transparent and in its proper location within the pupillary aperture. Its transparency depends on its highly regimented structure, the paucity of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cytoplasmic organelles, the very precise molecular character of its intracellular crystalline proteins, and on its maintenance of a critical state of dehydration. That dehydration is maintained primarily by excretion of electrolytes through an active sodium-potassium–dependent adenosinetriphosphatase pump, located mostly in the anterior lens epithelium.

The location of the lens within the pupillary aperture (with the iris resting on its anterior surface and its posterior surface embedded in a depression in the anterior surface of the vitreous) is maintained by a ring of transparent elastin-like fibers (the lens zonules or zonular fibers) stretching from the lens capsule to the nonpigmented ciliary epithelium. The exact arrangement of these fibers varies greatly by species. Contraction and relaxation of the ciliary muscles alters tension on these fibers and allows the lens to change shape or position, and thus to focus.

The health of the lens is almost totally dependent on the aqueous humor delivering nutrients and removing its waste products. Lens metabolism is primarily via anaerobic glycolysis. Glucose is delivered via the aqueous humor and is absorbed across the lens capsule, which is impermeable to most other substances. This metabolic peculiarity of the lens is vital in the understanding the development of diabetic cataracts (see later discussion).

20.1.1.4

### RETINA AND VITREOUS

The retina is the *raison d'être* for the entire globe. The cornea, lens, uveal tract, and sclera are simply a “supporting cast” to allow the retina to do its job of converting photons of visible light into electrical impulses, which are transmitted to the visual cortex of the brain. It is the most fascinating of the ocular tissues, yet at the same time the one that we can influence the least. It is one of the sad realities of ocular disease that we are often powerless spectators, able to view the evidence of active or previous retinal disease, yet with virtually no ability to influence it. Most frequently, at the time of clinical examination, the eye is already blind from retinal detachment, inherited photoreceptor disease, or the devastating effects of glaucoma.

The retina is, quite literally, an outpouching of brain tissue. It is formed from the neur ectoderm of the anterior half of the primitive optic vesicle. As that optic vesicle invaginates to form the optic cup, the presumptive retinal neur ectoderm is pushed into apposition with the neur ectoderm from the posterior half of that optic vesicle, which will form the retinal pigment epithelium (RPE). The proper development of the retina requires that proximity to the retinal pigment epithelium. This dependence of retina on the retinal pigment epithelium continues throughout life. It is impossible to review all significant features of the very complex retinal structure and function here, but those features that are most important in understanding the retinal diseases are as follows:

1. Macroscopically the retina resembles a slightly opaque vascularized membrane, resembling tissue paper, held against the RPE, choroid, and sclera by the gel-like vitreous. It is not actually attached to that RPE and/or choroid except at the optic disc and at its very periphery, where it becomes continuous with the epithelium of the pars plana of the ciliary body (the site of transition is known as the *ora ciliaris retinae*).
2. The retina consists of three layers of neurons (ganglion cells, inner nuclear layer, and outer nuclear layer) separated by cell-free layers created by the intermingling of the axons and dendrites of those neurons. The innermost layer, adjacent to the vitreous, is the nerve fiber layer. It is made up of the ganglion cell axons that, as they exit the globe, become the optic nerve. The RPE is usually listed as the outermost layer of the retina, but it is derived from the posterior half of the optic vesicle and is

## Pathologic Basis of Veterinary Disease, 4th Edition

---

not directly involved in vision. The RPE, anatomically and functionally, is more appropriately considered a part of the choroid. The combination of retina, RPE, choroid, and tapetum that is responsible for the ophthalmoscopic appearance of the posterior pole of the globe is known as the ocular fundus ([Fig. 20-3](#)).

3. The outer nuclear layer is formed by the cell bodies of the photoreceptors, which are specialized cilia containing photoactivated pigments, which are responsible for converting light into electrical impulses. These photoreceptors are embedded into crevices within the surface of the adjacent RPE, but there are no actual cellular junctions. This intimate contact is essential to allow the RPE to deliver nutrients to, and to remove waste products from, the metabolically demanding photoreceptors. The potential space between the photoreceptors and the RPE is the remnant of the lumen of the primary optic vesicle. It is in this space that hemorrhage, edema fluid, and inflammatory exudate accumulate, resulting in exudative retinal detachment.

1352

4. The inner (vitreal) half of the retina in most species is supplied by blood vessels entering the globe through the optic nerve. In contrast, the outer nuclear layer, photoreceptors, and RPE are totally dependent on diffusion of nutrients from the adjacent choroid. Separation of the retina from the RPE results in rapid ischemic degeneration of photoreceptors, and eventually of the outer nuclear layer. In the horse, in which retinal blood vessels are almost absent, the assumption is that the retina relies almost completely on choroidal diffusion to obtain nutrients, and the consequences of retinal detachment should therefore be even more devastating.

1354

5. The optic nerve is the continuation of the nerve fiber layer of ganglion cell axons into the brain and uses the preexistent tube formed by the embryonic optic stalk. Ganglion cell axons exit the globe through a series of perforations, known as the lamina cribrosa, in the sclera at the posterior pole of the globe. In most species, axons become myelinated at about the level of the lamina cribrosa, as they leave the globe. The combination of axons, myelin, and supporting glia on the vitreal side of that lamina cribrosa forms the optic disc. The amount of myelin and how far the myelinated fibers extend into the retina are responsible for the ophthalmoscopic appearance of the optic disc, which varies among species ([Fig. 20-4](#)). In dogs, the myelin extends several millimeters internal (anterior) to the lamina cribrosa and this is responsible for the prominence of the optic disc in that species. Because the optic nerve is a tract of the brain rather than a true peripheral nerve, the myelin is laid down by oligodendrocytes instead of Schwann cells (see [Chapter 14](#)).
6. Vision requires that the light gathered and refracted by the cornea is focused by the lens onto the photoreceptors. Light passes through the minimally absorptive inner two thirds of the retina so that most of it can be absorbed by the pigments within the photoreceptors. The electrical signal generated by activation of the photopigment is transmitted in a stepwise fashion from the outer nuclear layer to the neurons of the inner nuclear layer, then to the ganglion cells, and finally via the nerve fiber layer to the optic nerve and brain. The number of photoreceptors “feeding” to a single ganglion cell varies greatly among species and is one of the variables determining visual acuity and the efficacy of dim-light vision. Photons not absorbed on the initial pass through the photoreceptors will, in all domestic animals except the pig, then be reflected back by the cytoplasmic crystals embedded within the tapetum to stimulate the photoreceptors a second time. The tapetum is therefore assumed to be a choroidal adaptation to increase the efficiency of vision in dim light.

Fig. 20-3 Normal mammalian retina. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

Light passes through several layers of the retina before activating the rod and cone photoreceptor cells. The layers of the retina observed in the photomicrograph are represented in the adjacent diagram. The synapses between the cells of each layer of the retina are also illustrated.

Radial branches from blood vessels (arteries and veins)—located on the retinal surface—are interconnected by capillary beds present in the inner layers of the retina. Retinal capillary beds are lined by endothelial cells linked by tight junctions creating an internal blood-retinal barrier. An external retinal barrier is formed by tight junctions linking the cells of the pigmented epithelium.

Note that:

The nuclei of rods and cones are present in the outer nuclear layer.

The axons of the cones and rods project into the outer plexiform layer and synapse with dendrites of the bipolar cells.

Nuclei of the bipolar cells contribute to the inner nuclear layer. Axons of the bipolar cells synapse with dendrites of the ganglion cells in the inner plexiform layer.

Axons of the ganglion cells become part of the optic nerve.

Müller cells span most of the retina. The inner limiting membrane represents their basal lamina. Their nuclei form part of the inner nuclear layer.

The outer limiting membrane corresponds to junctional complexes (zonula adherens) between rods, cones, and Müller cells.

Horizontal cells synapse with several rods and cones.

Amacrine cells synapse with axons of bipolar cells and dendrites of ganglion cells.

**Fig. 20-4 Normal optic disc, dog.** The dense fibrous tunic of the sclera becomes fenestrated to permit the exit of the nerve, creating the lamina cribrosa (arrow). H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The vitreous is an optically clear, gelatinous mass that fills the interior of the globe from the back of the lens to the retina. It is about 99% water, with collagen and hyaluronic acid making up most of the remaining 1%. Little is known about the production and turnover of the vitreous humor. It is thought to be made mostly by secretion from nonneuronal cells of the retina and the nonpigmented epithelium of the ciliary body. The vitreous contains only a scattering of histiocyte-like cells, known as hyalocytes, and a few fibroblasts. Along the anterior surface of the vitreous is a shallow depression known as the hyaloid fossa, in which lies the posterior surface of the lens. The anterior surface of the vitreous undergoes condensation to form the anterior hyaloid membrane, which separates the vitreous from the aqueous humor. The vitreous seems to function mainly to maintain the shape of the globe and to help support the retina in its normal position against the RPE and choroid.

### 20.1.1.5

#### EYELIDS, CONJUNCTIVA, AND ORBIT

The central theme in ophthalmology is the degree to which proper ocular function rests on the ability of the critical visual tissues, such as the retina and lens, to function thanks to a carefully controlled, protected environment. The eye is thus entirely dependent on a long list of factors in a “supporting cast” to protect the sensitive visual tissues against the external environment. The first line of defense is the eyelids, conjunctiva, and bones of the orbit that create a wall around the globe. That protective wall is designed to let in light and nutrients, but to exclude the many elements of the external environment that might injure this very sensitive organ.

1354

1355

From the perspective of a pathologist, the diseases of the eyelids, conjunctiva, and orbit are much less intriguing than those of the globe itself. From a clinical perspective, however, the diseases of the eyelid and conjunctiva form a major part of what the primary care veterinarian is likely to diagnose and treat.

### 20.1.1.5.1

#### Eyelids

The epithelium of the eyelids develops from the surface ectoderm adjacent to the cornea. After separation of the lens vesicle, the surface ectoderm regains continuity to form the cornea. Ectoderm at the periphery of the cornea then migrates over the surface of the embryonic cornea, accompanied by some underlying periocular mesenchyme to form the eyelids. The ectoderm will form the surface epithelium and glands; the accompanying periocular mesenchyme will form the deeper dermis and the eyelid muscles. These ingrowing lid buds fuse with each other over the central cornea. How long this fusion persists varies with the species. In dogs and cats, it persists until about 2 weeks after birth and provides the immature cornea with a secure, sterile environment in which to complete its embryologic development.

The mature eyelids are moveable folds of skin that slide across the surface of the cornea on a film of mucus and fluid known as the tear film. This blinking movement serves to help distribute the protective tear film across the corneal surface and to remove unwanted particulate debris from the corneal surface. Each eyelid has an anterior surface of haired skin, with all of the adnexal glands as seen in skin anywhere else. The dermis is modified by the addition of striated muscle (orbicularis oculi and levator muscles). The inner surface of the eyelid, which rests against the cornea, is covered by a mucus membrane known as the palpebral conjunctiva (see conjunctiva section). The site of transformation from eyelid skin to palpebral conjunctiva at the eyelid margin is characterized by the presence of a row of very large modified sebaceous glands known as Meibomian glands and by the emergence of several rows of large modified hairs that are the eyelid cilia (eyelashes). The Meibomian glands contribute a lipid component to the tear film, which aids in the dispersal of the aqueous component of the tear film and helps prevent evaporation. The cilia are largest and most numerous along the margin of the upper eyelid; they may be infrequent or absent along the lower eyelid.

### 20.1.1.5.2

#### Conjunctiva

The conjunctiva is a mucous membrane extending from the palpebral margin of the eyelid to the periphery of the cornea. That portion of conjunctiva that covers the posterior surface of the eyelid is the palpebral conjunctiva. That portion attached to the surface of the globe, and continuous with the peripheral cornea at the limbus, is the bulbar conjunctiva.

The palpebral conjunctiva consists of stratified squamous nonkeratinized epithelium near its origin at the eyelid margin but quickly becomes stratified columnar epithelium with numerous goblet cells. At the base of the eyelid, it is reflected back onto the surface of the sclera. Now named the bulbar conjunctiva, it extends over the eyeball as far as the periphery of the cornea. The epithelium of the bulbar conjunctiva lacks goblet cells. It becomes continuous with the corneal epithelium at the limbus. At that junction between bulbar conjunctiva and corneal epithelium, there is a population of germinal cells that are the permanent replicative cells of the corneal epithelium. They are the source of replacement corneal epithelial cells in cases of persistent corneal ulceration.

The space between the palpebral and bulbar conjunctiva is the conjunctival sac. The space between the upper and lower eyelid is known as the palpebral fissure. The medial (nasal) limit of the palpebral fissure (where the upper and lower eyelids join) is the medial canthus. The lateral (temporal) margin of the palpebral fissure is known as the lateral canthus. It is the palpebral fissure that determines what most people would regard as the “shape of the eye,” which has considerable importance in the breeding of

## Pathologic Basis of Veterinary Disease, 4th Edition

purebred dogs. It is the careless genetic manipulation of the shape of the palpebral fissure that is responsible for the frequency of some of the most common eyelid diseases (see later discussion under Entropion and Ectropion).

The lamina propria of both the palpebral and bulbar conjunctiva resembles the lamina propria of any other mucus membrane. It has an abundance of blood vessels, loose connective tissue, variable numbers of lymphocytes, plasma cells, and diffuse lymphoid tissue and lymphoid nodules (MALT). The MALT responds immunologically to the microbial flora within the conjunctival sac. In patients with chronic conjunctivitis, the lymphoid nodules are often grossly visible, indicating the intensity and duration of the response of the MALT to antigenic stimuli.

The ventral conjunctiva, as it transforms from palpebral to bulbar conjunctiva, undergoes an additional specialization in the form of the third eyelid or nictitating membrane. This large fold of conjunctiva protrudes from the ventral-medial canthus over the anterior surface of the cornea, and contains a central supporting plate of cartilage and a stroma of dense fibrous tissue, containing an accessory lacrimal gland. Both its anterior and posterior surfaces are covered by stratified squamous nonkeratinized epithelium. In most domestic species, its movement is passive, serving to cover the globe and provide an extra level of protection when the globe is retracted into the orbit by the retractor bulbi muscle.

1355

1356

### 20.1.1.5.3

#### Orbit

The orbit is the bony fossa that surrounds most of the globe, except the cornea, and separates the globe from the brain. Along its posterior border are numerous foramina through which blood vessels and nerves reach or leave the globe. The orbit is formed by the fusion of five to seven bones, depending on the species. It is a complete bony shell, except in dogs, cats, and pigs, in which the dorsal roof of the orbit is formed only by the supraorbital ligament that extends from the frontal bone to the zygomatic bone, leaving the dorsal orbit incomplete. The orbit contains not only the globe itself but also the extraocular muscles, abundant fat, lacrimal gland, zygomatic salivary gland, and all the muscles and nerves that support these structures.

The lacrimal gland is a specialized serous salivary gland located in the orbit, dorsolateral to the eyeball. Along with the histologically similar gland of the third eyelid, it is responsible for the production of the serous component of tears. It empties through 15 to 20 small excretory ducts at the lateral part of the fornix of the superior conjunctival sac.

It is unclear how much interdependence there is between the ocular and orbital embryologic development. On one hand, animals with severe microphthalmia often have a relatively normal orbit, but usually there is some reduction in size and distortion of shape. It may be that the critical issue is the stage of embryogenesis at which the developing globe is injured and subsequently atrophies (remember that most microphthalmia in domestic animals is “secondary” and is due to in utero atrophy rather than true hypoplasia).

### 20.1.2

#### PORTALS OF ENTRY

### 20.1.2.1

#### CORNEA

Portals of entry into the cornea are listed in [Box 20-1](#). Injury to the cornea may arise from altered homeostasis of the corneal surface, by penetrating injury through the surface epithelium, secondary to

## Pathologic Basis of Veterinary Disease, 4th Edition

---

injury to corneal endothelium, or rarely by migration into the cornea from the blood vessels at the limbus. Regardless of the route of entry, virtually all significant corneal diseases reflect stromal injury, whether this stromal injury was the primary lesion or simply a consequence of injury to the surface epithelium or to the endothelium of the cornea.

### 20.1.2.2 UVEA

Portals of entry into the uvea are listed in [Box 20-2](#). Microbes and other injurious agents enter the uvea via the blood stream (hematogenous), penetrating injury, or aqueous or vitreous. Hematogenous entry is used by toxins, infectious agents, and metastatic neoplasia. Injury to the blood vessels themselves (thrombosis, occlusion by neoplastic emboli) may cause ischemic damage. Penetrating injury provides infectious agents entry into one or more of the ocular chambers, causing either uveal injury either by production of toxins or (more often) by stimulating a uveal inflammatory response. Injury that causes lens rupture can initiate a phacoclastic uveitis (see later discussion). Chemical mediators of inflammation released from an injured cornea, lens, or retina diffuse into and throughout the aqueous or vitreous, thus providing the opportunity for additional injury in contiguous tissues.

### 20.1.2.3 LENS

Portals of entry into the lens are listed in [Box 20-3](#). Although the lens is occasionally injured by a direct perforating injury (see later discussion under Phacoclastic Uveitis) or becomes displaced by blunt trauma (lens luxation), the vast majority of injuries to the lens are related to defective lens nutrition. This involves either inadequate delivery of nutrients because of defective flow of aqueous humor or chemically abnormal aqueous humor. That aqueous humor may contain by-products of intraocular necrosis or inflammation, or excessive/deficient levels of specific chemicals. Common examples include cataracts caused by excessive glucose levels in animals with diabetes mellitus and cataracts associated with systemic hypocalcemia. Degenerative changes in the lens are also seen in dogs with inherited photoreceptor disorders (so-called progressive retinal atrophy), probably caused by diffusion of toxic by-products of photoreceptor degeneration. Inherited cataracts in dogs are the single most frequent type of cataract seen in veterinary practice, but virtually nothing is known about the specific biochemical pathogenesis.

Among the more exotic causes of lens injury are injury from therapeutic radiation; electrical shock, including lightning strike; and penetrating intralenticular metallic foreign bodies. Dietary imbalances, excessive sunlight exposure, and parasitic migration are common causes of cataracts in some nonmammalian species (especially fish) but have rarely been reported in domestic mammals. Cataracts have been reported in puppies and wolf cubs fed a commercial milk replacer, and in kittens fed feline milk replacer. Cataract development was attributed to a dietary deficiency of arginine, although the precise nature of the dietary deficiency was not identified in every instance.

Because the lens is avascular and surrounded by a dense collagenous capsule, it is relatively impervious to the entry of infectious agents from elsewhere in the globe. The one rare exception in domestic mammals is the seemingly specific targeting of the lens capsule by systemic aspergillosis and presumably by other species of hyphal fungi occurring as a sequelae to mycotic abomasitis in calves or opportunistic mycoses in dogs immunosuppressed by cancer chemotherapy. These fungi exhibit a tropism for basement membranes throughout the body, including the lens capsule. In rabbits, the lens capsule is frequently penetrated by the

## Pathologic Basis of Veterinary Disease, 4th Edition

protozoon *Encephalitozoon cuniculi*, which causes spontaneous lens rupture. In fish, cataracts induced by the selective intralenticular penetration by fluke larvae are exceedingly prevalent. Several viral diseases, notably bovine viral diarrhea, are occasionally associated with congenital cataracts as a consequence of generalized systemic infection in utero before the establishment of the blood-eye barrier.

20.1.2.4

### RETINA AND VITREOUS

It has been said that anything in notable excess or deficiency is harmful. That statement is particularly applicable to the retina, which, despite its sheltered intraocular niche, probably is injured by a wider range of noxious stimuli arriving by a wider variety of routes than any other tissue in the body.

Portals of entry into the retina are listed in [Box 20-4](#). The retina can be injured by light and other types of radiation arriving through the cornea and lens, by hematogenous dissemination of chemical or infectious agents, by objects penetrating through the cornea or through the sclera, and by microorganisms arriving via the optic nerve. Because the retina is part of the brain, it is susceptible to most of the infectious, degenerative, and metabolic diseases of the brain, including the storage diseases. Exactly how frequently the retina is involved in diseases affecting primarily the brain is unknown, but the risk appears to be quite low.

The retina is sensitive to injury from chemical mediators of inflammation and toxic products of infectious agents within the vitreous and is particularly sensitive to increased intraocular pressure. Especially in purebred dogs, there is also a huge list of inherited defects in photoreceptor metabolism, which result in progressive destruction of photoreceptors and their nuclei.

The most important and most frequent causes of injury are those related to retinal detachment (see later discussion), increased intraocular pressure, vascular hypertension, and genetically determined photoreceptor diseases. It is important to view this list in perspective. Despite the long list of potentially injurious stimuli and the innumerable routes by which such stimuli can impact the retina, retinal disease is actually quite infrequent.

### EYELIDS, CONJUNCTIVA, AND ORBIT

20.1.2.5.1

#### Eyelids

The outer surface of the eyelid is skin and therefore is susceptible to the same diseases as the skin elsewhere on the body. For palpebral skin, the portals of entry are the same as for skin at other sites:

1. Through the skin's surface or through adnexal glands by colonization of niche-adapted infectious agents
2. Penetrating injury
3. Hematogenous localization

20.1.2.5.2

#### Conjunctiva

The conjunctiva is a mucous membrane similar in structure to other mucous membranes and is therefore susceptible to injury from the same range of physical and chemical injuries affecting any other mucous membrane. The routes of entry are predictable:

1. Colonization of the epithelial surface by niche-adapted infectious agents
2. Absorption of injurious antigenic stimuli across an intact epithelium
3. Implantation via penetrating injury
4. Direct physical or chemical injury to the epithelial surface, allowing opportunistic infection
5. Hematogenous localization

20.1.2.5.3

#### Orbit

Portals of entry into the orbit are as follows:

1. Orbital fractures from external trauma
2. Extension of inflammatory or neoplastic disease originating within the gingiva or the nasal cavity
3. Extension of intraocular inflammatory or neoplastic disease through the sclera
4. Direct extension of inflammatory or neoplastic foci from the conjunctiva or eyelid

## Pathologic Basis of Veterinary Disease, 4th Edition

---

5. Penetrating injuries through the skin or upwardly through the mouth, or migrating foreign bodies implanting infectious agents
6. Hematogenous localization of microorganisms, neoplasms, and influx of antibodies in immune-mediated diseases (muscle, lacrimal gland)
7. Extension from the cranial vault via the optic nerve or through one of the other foramina; this is rare

Of these portals of entry, infectious orbital cellulitis resulting from penetrating foreign body or migration from tooth root cellulitis is the most common. In dogs and cats, spread of osteolytic nasal carcinoma, oral squamous cell carcinoma, or malignant melanoma into the orbit is relatively frequent. In cattle, the orbit is a frequent location for metastatic malignant lymphoma in those animals that survive long enough with the disease.

### 20.1.3 DEFENSE MECHANISMS

#### 20.1.3.1 CORNEA

The cornea is defended against injury by its protected anatomic location, by several reflexes, and by the tear film ([Box 20-5](#)). Passive (anatomic) protection is provided by the eyelids, the eyelashes, and the bony orbit. Various reflexes are activated by mechanical stimulation of eyelids, eyelashes, or the cornea itself. The blink reflex causes the eyelids to close when the eyelids or eyelashes are stimulated by contact with any solid material or even strong air currents. The menace reflex causes the eyelids to blink when there is visual perception of a threat to the globe. The corneal reflex causes the eyelids to close when the cornea itself is irritated by external stimuli. Reflex retraction of the globe into the orbit, with subsequent passive sliding of the third eyelid to cover the cornea, occurs in response to corneal trauma.

---

lamina propria. It not only provides the majority of the nourishment for the avascular cornea, but also provides a mucus coat to prevent evaporation of the protective fluid, soluble antibacterial chemicals, and a flushing action to protect the cornea against colonization by bacteria and fungi that live in the conjunctival sac.

20.1.3.2

### UVEA

The uveal tract, like any other lamina propria, is in free communication with the peripheral blood and is therefore not protected against any noxious agents in circulation. It is protected from physical injury (as are most other parts of the globe) by the thick fibrous tunic of the sclera and by the bony orbit.

Direct uveal injury, however, seems to be less important to the globe than the spread of the uveal disease to other parts of the eye that are less able to resist an insult or regenerate (particularly the lens and retina). The protection of other portions of the globe from inflammation in the uvea rests on two main mechanisms: the blood-ocular barrier, and the unique immunologic phenomenon known as anterior chamber immune deviation.

The blood-ocular barrier is created by tight junctions between endothelial cells of the iris and retinal blood vessels, and tight junctions between adjacent epithelial cells of the inner nonpigmented ciliary epithelium and the retinal pigment epithelium. Unless the damage to the uvea itself is so severe as to disrupt these tight junctions, they prevent most chemical and infectious agents from gaining access to vulnerable intraocular tissues, such as the lens and retina.

The location of this barrier is important in understanding the different reactions to injury by different parts of the uveal tract. For example, the presence of tight junctions between the RPE cells is extremely important in preventing exudate from within the choroid gaining access to the subretinal space. Subretinal fluid accumulation can cause vision-threatening retinal detachment, so the blood-eye barrier at that site provides important protection.

In the anterior chamber, however, the situation is quite different. Here the barrier is at the level of the endothelial cells of the iris. During any substantial inflammation, this barrier is broken as part of the increased vascular permeability inherent in any acute inflammation. This allows infectious agents, inflammatory mediators, and leukocytes to flood into the stroma of the iris. Because the iris has no “barrier” along its anterior surface, these agents, cells, and chemicals then quickly diffuse into aqueous humor of the anterior chamber. From here, they may disperse throughout the globe and damage the lens or even the retina.

Anterior chamber-associated immune deviation (ACAID) is a specialized immune response by which infectious agents and many other antigens introduced into the anterior chamber cause only a highly controlled immune response that effectively eliminates the provoking antigen, while producing minimal bystander tissue injury that would threaten nearby ocular tissue. ACAID protects the eye from antigen-specific, immune-mediated injury from delayed-type hypersensitivity (DTH). The eye contains no lymphoid tissue. To initiate an immune response, antigens within the anterior chamber must first be captured by intraocular antigen presenting cells, exit the globe through the normal aqueous outflow pathways, and reach the marginal zones of the spleen. Here antigen-specific T cells are activated to differentiate into regulatory cells that interfere with the induction of DTH, thus muting DTH and sparing the eye from inflammation induced by DTH.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 20.1.3.3 LENS

The defenses of the lens against injury are almost purely passive. They are the fibrous tunic of the cornea and sclera, the bony orbit, the eyelids, and a thick collagenous resilient lens capsule.

### 20.1.3.4 RETINA AND VITREOUS

The retina and vitreous, like the lens, rely mostly on their protected intraocular niche, and like the lens, its active defense mechanisms are negligible. They are protected from most physical and chemical injury by the bony orbit, the fibrous shell of cornea and sclera, and by the uvea and from infectious (and, to some extent, from toxic and metabolic) diseases by the blood-eye barrier created by tight junctions between RPE cells and by the tight junctions of the retinal vascular endothelium. The retina has essentially no defense against infectious agents, radiation, or noxious chemicals arriving through the vitreous. Ischemic injury is a major threat to retinal viability. It is protected by having an autoregulated vascular system that allows retinal perfusion to remain relatively normal despite wide fluctuations in systemic blood pressure. The injured retina also produces angiogenic growth factors and has a powerful system of scavengers to counteract the damaging effects of excitatory neurotoxins, nitric oxide, and other potentially damaging by-products of ischemia. The retina and vitreous have no resident phagocytes or other cellular components of the immune system.

1359  
1360

### 20.1.3.5 EYELIDS, CONJUNCTIVA, AND ORBIT

#### 20.1.3.5.1 Eyelids

Like skin anywhere else, the defenses of eyelid against injury include both structural and cellular defenses, including hair, keratin, epithelial tight junctions, and a potent intraepithelial and superficial dermal immune system (see discussion on skin). Like skin, it becomes susceptible to infectious disease when those defenses are compromised by excessive moisture, metabolic disease, or mechanical injury. The eyelid is susceptible to all of the same infectious, nutritional, and immune diseases as skin in any other location.

#### 20.1.3.5.2 Conjunctiva

The conjunctiva is protected from most physical and chemical injuries by the eyelids and by the tear film. It has tight junctions between the epithelial cells to prevent easy access by infectious or chemical agents into the underlying lamina propria. It is capable of rapid replication in the event of injury, and readily undergoes squamous metaplasia as an adaptive survival mechanism in response to chronic low grade irritation of any type. The resident mucosal immune system (MALT) functions similarly to immune systems in other mucosal sites, such as the upper respiratory tract, lungs (BALT), and gastrointestinal tract (GALT) (see [Chapter 13](#)).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 20.1.4 RESPONSE TO INJURY

#### 20.1.4.1 CORNEA

Injury to the corneal epithelium occurs from chemical or physical injury, from deficiency in the quantity or quality of the tear film, or by colonization of the corneal epithelium by infectious agents specifically adapted to that environmental niche. Common examples of such damage include abrasion from misdirected eyelashes or improperly structured eyelids, irritating plant or other foreign bodies within the conjunctival sac, or lacerations inflicted in the course of fighting or running through heavy brush. The cornea is also very susceptible to changes in the quality or quantity of the tear film that may result from primary disease of the lacrimal gland or from desiccation caused by enlargement of the globe or impaired closure of the eyelids.

The corneal endothelium may be injured by increased intraocular pressure (glaucoma), mechanical damage from an anteriorly displaced lens, or from injury mediated by leukocytes (so-called corneal endothelialitis).

The corneal stroma is most frequently injured as a sequela to epithelial damage. It may also be directly injured by lacerations and penetrating injury, implantation of infectious agents subsequent to penetrating injury, or (rarely) by percolation of chemical or infectious agents into the corneal stroma from the blood vessels at the limbus. Injury to the corneal endothelium will also affect the stroma, allowing the dehydrated but strongly hydrophilic stroma to absorb fluid from the aqueous humor. This results in corneal edema and substantial visual impairment ([Box 20-6](#)).

The great majority of corneal lesions encountered in clinical practice result from epithelial injury as a result of trauma or desiccation. Almost all corneal diseases listed in clinical textbooks reflect one or more of only three pathologic processes: adaptive cutaneous metaplasia in response to mild irritation, epithelial and/or stromal necrosis, and repair (wound healing) ([Box 20-7](#)). The varied clinical manifestations of these three fundamental processes are often given specific clinical names that serve to confuse rather than clarify.

#### 20.1.4.1.1 Adaptive Cutaneous Metaplasia to Mild Persistent Irritation

The usual response of the cornea to persistent mild irritation is cutaneous metaplasia, which is a combination of keratinization, epithelial hyperplasia, epithelial pigmentation, subepithelial fibrosis, and vascularization ([Figs. 20-5](#) and [20-6](#)). In short, a cornea that is challenged to adapt to mild persistent irritation does so by recalling its genetic heritage as skin, and comes to resemble skin in every way except for the acquisition of hair follicles. Not all examples of cutaneous metaplasia involve the entire range of adaptive changes; it is possible, for example, to have keratinization without pigmentation, or epidermal metaplasia without accompanying stromal fibrosis and vascularization. It depends on the nature of the irritation. The most common causes for such adaptation include chronic desiccation and mechanical irritation from eyelid diseases, such as entropion or anomalous placement or direction of eyelashes. Desiccation may result from defective production of tears as in keratoconjunctivitis sicca, from improper distribution of tears because of improper eyelid structure or function, or because of ocular enlargement that prevents the lids from closing. Because the cornea is permitted to exist in its privileged state only because it is constantly bathed in a protective and nourishing tear film, the partial or complete removal of that tear film represents a significant challenge to corneal homeostasis. If the change occurs slowly, the cornea will successfully adapt by undergoing cutaneous metaplasia. If, on the other hand, the desiccation occurs very rapidly, then the cornea will likely ulcerate.

Fig. 20-6 **Corneal cutaneous metaplasia, keratoconjunctivitis sicca, cornea, dog.** Chronic desiccation has caused adaptive epithelial hyperplasia, epithelial and stromal pigmentation, and stromal scarring. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Cutaneous metaplasia is a complex event that probably reflects the failure of conjunctival epithelial cells and stroma to acquire corneal phenotypes as they grow toward the center of the cornea to replace injured corneal tissue. The corneal epithelium has a finite number of replicative cycles. Persistent injury that exceeds the replicative ability of the corneal epithelium itself will require ingrowth of germinal cells that reside in the bulbar conjunctiva at the limbus. Similarly, injured corneal stroma will often need to recruit fibroblasts from the adjacent conjunctival lamina propria or sclera. What chemical signals are required to induce conjunctival or scleral tissue to undergo maturation into more appropriate “corneal” structure remain unknown.

1361

1362

Some of the lesions of cutaneous metaplasia are reversible, albeit only very slowly. Stromal fibrosis, however, is a permanent change and the corneal stroma will never again recover complete transparency (see discussion on corneal wound healing). It is easy to think of corneal cutaneous metaplasia as an undesirable pathologic event, but in fact it is an eye-saving response to a pathologic change in the corneal environment. Failure to undergo cutaneous metaplasia would lead to corneal disintegration and subsequent destruction of all of the intraocular tissues.

Clinical entities characterized by corneal cutaneous metaplasia include pigmentary keratitis (corneal desiccation in brachycephalic dogs), keratoconjunctivitis sicca, band keratopathy secondary to eyelid

## Pathologic Basis of Veterinary Disease, 4th Edition

closure defects, chronic keratitis secondary to irritation from eyelids or eyelashes, and chronic corneal desiccation as a consequence of chronic glaucoma.

20.1.4.1.1.3

### Epithelial and/or stromal necrosis

Injuries to the cornea that occur too quickly or with too much severity to permit cutaneous metaplasia result in corneal necrosis. Because most of the injuries are from external insults, it is the corneal epithelium that is most commonly affected. The usual result is corneal ulceration. The causes are numerous, including rapidly progressing desiccation, severe mechanical injury, injury from exogenous chemicals, and a few niche-adapted infectious diseases such as herpesvirus infection in cats and *Moraxella bovis* infection in cattle.

Following full-thickness epithelial loss, there is immediate osmotic absorption of water from the tear film into the anterior stroma, resulting in focal superficial stromal edema that is the clinical hallmark of corneal ulceration. The absorption of water increases the spacing between the stromal collagen fibers and results in increased scattering of light, which clinically appears as corneal opacity. Coloring the tear film with water-soluble dyes like fluorescein is a very common clinical diagnostic technique to accentuate the edema within the stroma. Within hours, neutrophils from that tear film are also absorbed into the cornea (Fig. 20-7). In small “physiologic” numbers, they aid in defending the denuded cornea against opportunistic infection, provide growth factors for subsequent wound healing, and help with a small amount of corneal stromal débridement necessary for wound healing. If the wound becomes infected and the neutrophils migrate from the tear film and limbus in large numbers, their lytic enzymes create enough bystander injury to result in stromal destruction, known as suppurative keratomalacia (Fig. 20-8).

**Fig. 20-7 Early healing, shallow ulcer, cornea, dog.** The corneal epithelium is sliding along the surface of the denuded intact stroma that now has substantial staining pallor and separation of collagen fibers typical of edema. Numerous neutrophils have migrated into the stroma from the tear film. The neutrophils, although necessary in moderation, have the potential to cause enzymatic digestion of the stroma (keratomalacia) and are sources of fibroblastic and angioblastic growth factors. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-8 Suppurative keratomalacia, enucleated globe, horse.** An initial corneal laceration became infected with *Pseudomonas* spp. The infection has resulted in proteolytic destruction of the stroma caused mostly by the release of digestive enzymes from neutrophils in the inflammatory exudate. Healing will result in a large amount of stromal scarring. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

1362

Corneal injuries of greater magnitude result in deep ulcers with substantial stromal loss, even to the point of disappearance of the entire stroma exterior to Descemet's membrane. This is most commonly seen in rapidly progressing ulcers contaminated with bacteria, resulting in neutrophil-induced keratomalacia. These ulcers, known as "melting ulcers," may progress over just a day or two to full-thickness stromal dissolution. Descemet's membrane is the last barrier. It will bulge anteriorly into the defect created by the loss of the overlying stroma and epithelium to create a descemetocoele (Fig. 20-9). In most instances, this fragile membrane (Descemet's membrane) ruptures, resulting in a perforating ulcer, which leads to the loss of anterior chamber fluid and the strong probability of iris prolapse. Iris prolapse may also result from corneal perforation from trauma.

1363

Keratitis is a common clinical term indicating inflammation of the cornea. Because the normal cornea is avascular, true inflammation cannot occur until later in the disease process, after the injured cornea has been vascularized as part of wound healing (see later discussion). Nonetheless, corneal ulcers are very susceptible to opportunistic infection from normal conjunctival flora or organisms from the

## Pathologic Basis of Veterinary Disease, 4th Edition

environment. This is probably particularly true of mycotic keratitis in horses, particularly when the fungal infection is given an unfair advantage because of inappropriate use of antibiotics and/or corticosteroids in the management of minor corneal lacerations. The presence of such organisms within the cornea results in a marked acceleration of leukocyte immigration from the tear film and blood vessels of the limbus. Although these leukocytes may be effective in neutralizing the infectious agent, they usually create substantial bystander injury to the stroma or the epithelium, resulting in a delay in wound healing and an increase in scarring.

**Fig. 20-9 Deep central corneal ulcer (with descemetocoele and early iris prolapse), dog.** Note the diffuse corneal edema (diffuse gray appearance) caused mostly by imbibition of tear fluid, with some contribution from the blood vessels which are growing (angiogenesis) into the injured cornea as part of wound healing (the circumferential red “brush border” from the limbus). (*Courtesy Dr. J. Wolfer, Islington Animal Clinic.*)

20.1.4.1.2

### Repair (Wound Healing)

Those injuries limited to just a portion of the epithelial thickness will be rapidly repaired by epithelial sliding and eventual mitotic regeneration. Such injuries are unlikely to ever receive veterinary attention. Deeper defects that involve the full thickness of the epithelium and varying depths of stroma initiate a stereotypic series of events that are clinically significant, easily observed in clinical practice, and amenable to both medical and surgical intervention. Because the cornea is optically clear and readily accessible for continuous observation following injury, it is a favorite model for the *in vivo* study of the basic events of wound healing in mammalian tissue. From a pragmatic clinical perspective, the vast

## Pathologic Basis of Veterinary Disease, 4th Edition

---

majority of corneal lesions encountered in clinical practice are already past the stage of initial injury and are at the stage of corneal wound healing. If healing is less than optimal, an array of antimicrobial agents, surgical procedures, and chemical agents to modify the wound healing response is commonly used.

Most models of corneal wound healing use a mild, controlled nonseptic epithelial injury. The sequence of events and the biochemical signaling involved in such injury are not necessarily the same as those in naturally occurring massive corneal injuries and subsequent infections seen in veterinary practice, but nonetheless these carefully controlled models provide the only information available.

Following full-thickness destruction of a portion of the corneal epithelium, the sequence of events is depicted in [Fig. 20-10](#). Briefly, the injured epithelial cells release cytokines, such as interleukin-1 and platelet-derived growth factor (PDGF). Within minutes of lethal epithelial injury, these chemical mediators cause necrosis and/or apoptosis of stromal cells within the very superficial corneal stroma. At the same time, injured epithelial cells at the margin of the ulcer release epidermal growth factor (EGF), keratocyte growth factor (KGF), and hepatocyte growth factor (HGF) to stimulate epithelial migration and proliferation. Additionally, the production of these growth factors is up-regulated in the tear film.

The increase in EGF and other growth factors results in flattening and sliding of viable suprabasilar epithelial cells from the adjacent intact epithelium. These cells dissolve their intercellular junctions and

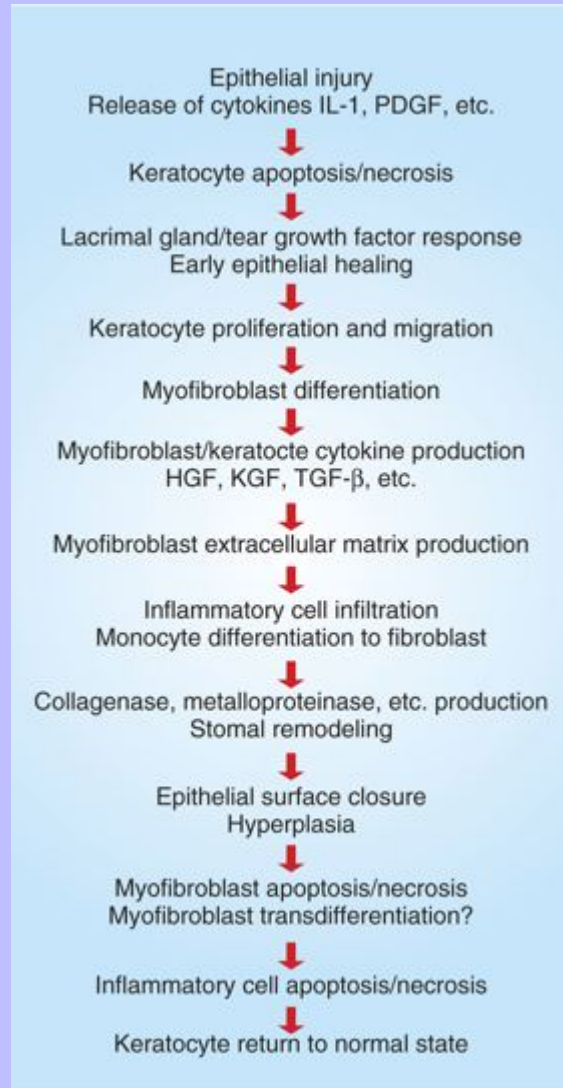

1363

migrate across the exposed stromal surface, adhering to a temporary scaffold of fibronectin and other adhesion molecules ([Fig. 20-11](#)). As long as the underlying stroma is healthy enough to support epithelial migration, excessive numbers of neutrophils are not present, and if the event that caused the original corneal injury is no longer active, those epithelial cells will slide with remarkable speed (as much as 1 mm per day) across the denuded surface in an attempt to close the defect. There are many other cytokines and adhesion molecules involved in corneal epithelial sliding and regeneration, suggesting that rapid sealing of the defect must be exceedingly important. Closure of the defect by even a thin layer of epithelium halts the continued recruitment of neutrophils, which are responsible for the keratomalacia, vision-impairing stromal fibroplasia, and vascularization from the limbus. Closure of the corneal defect also prevents further edema and limits access by potentially injurious infectious agents.

1364

Fig. 20-10 **Schematic diagram of the corneal wound healing cascade.**

*HGF*, Hepatocyte growth factor; *IL-1*, interleukin-1; *KGF*, keratocyte growth factor; *PDGF*, platelet-derived growth factor; *TGF- $\beta$* , transforming growth factor- $\beta$ . (Redrawn from Klenkler B, Sheardown H: Exp Eye Res 79:677-688, 2004.)

**Fig. 20-11 Corneal epithelial cell migration (epithelial sliding), early wound healing, cornea, dog.** Corneal epithelial cells are migrating (sliding) to cover the corneal ulcer (*right*). The stroma is edematous and contains a few neutrophils derived from the tear film. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Lagging behind the epithelial activation and sliding, which occur within minutes to hours of injury, is rebuilding of the injured stroma, which starts within a few days. It is not clear how the cornea recognizes the need for stromal rebuilding. There are some cases in which even a deep stromal defect does not initiate ingrowth of fibroblasts and blood vessels to rebuild the stroma. Instead the epithelium simply slides across whatever small amount of normal stroma remains. This results in an optically clear, but precariously thin, healed cornea (Fig. 20-12). Migration of neutrophils from the tear film and from the limbus into the corneal wound is a powerful stimulus for the recruitment of both blood vessels and fibroblasts from the limbus. Neutrophil immigration begins about 12 hours after mild injury in response to chemotactic factors released by injured epithelium and stroma. This delay in neutrophil recruitment presumably allows the epithelium to slide and seal small defects, and thus prevents excessive immigration of neutrophils (and its negative consequences as outlined later). Additional stimulation of stromal fibroplasia and angiogenesis comes from release of growth factors, such as PDGF, vascular endothelial growth factor (VEGF), and transforming growth factor- $\beta$  (TGF- $\beta$ ) from the injured epithelium, migrating neutrophils, and the injured stromal keratocytes. Not only does injury stimulate activation and migration of fibroblasts and angioblasts from the limbus, but it also changes the morphology and activity of the resident stromal fibroblasts (keratocytes). These cells undergo myofibroblastic metaplasia, become mobile and contractile, and produce increased amounts of various matrix proteins, growth factors, and metalloproteinases essential for stromal remodeling.

1364

**Fig. 20-12 Chronic descemetocoele, cornea, dog.** On the right, at the site of a former deep corneal ulcer, the epithelium has healed by corneal epithelial cell migration (sliding) into the ulcer, with subsequent epithelial hyperplasia and return of the corneal epithelium to normal or even increased thickness. However, because there has been no replacement or remodeling of the stroma (*right*), the epithelium is positioned directly on the surface of Descemet's membrane instead of on a reconstituted fibrous stroma. This process is "unsuccessful" wound healing, because the "healed" cornea, lacking stroma, is too fragile to survive. Masson trichrome stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The histologic events of stromal rebuilding following significant injury are less complicated than are the innumerable biochemical signaling interactions involved. Mild stromal injuries are repaired by in situ enlargement and sluggish proliferation of resident keratocytes, which undergo fibroblastic metaplasia. Following significant stromal injury, however, repair using just local keratocytes/monocytes is not adequate. Such repair must await the arrival of reinforcements in the form of fibroblasts and blood vessels from the limbus. Histologically, enlargement and hyperchromasia of limbal fibroblasts and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

angioblasts is visible within a day or two of injury, but detectable migration is not evident until about 4 days. Fibroblasts and blood vessels, preceded by a halo of edema and stromal proteolysis, migrate with a maximum speed of 1 mm per day until they reach the site of injury (Fig. 20-13). Here, they rebuild the injured stroma to provide a scaffold suitable for the migration, adhesion, and eventual normalization of the epithelium. Over time, this fibroblastic-angioblastic matrix of granulation tissue matures to histologically resemble normal stroma. However, it is never able to replicate the very specific lamellar structure of normal stroma and even with optimal stromal wound healing, corneal clarity is permanently impaired.

**Fig. 20-13 Normal wound healing, cornea, dog.** Following shallow ulceration that had damaged both the epithelium and the superficial stroma, the stroma is repaired and returned to near normal function by ingrowth of blood vessels and fibroblasts (wound healing) from the limbus. Such repair of the stroma is usually a prerequisite for epithelial regeneration following any large corneal ulceration. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

It is worth mentioning here that a lamellar ingrowth of blood vessels from the limbus into the middle third of a perfectly normal corneal stroma occurs as a bystander effect of chronic uveitis (see section on uveitis: Delayed Responses to Injury).

To summarize, the epithelial and stromal events of wound healing are stimulated by a complex interaction of dozens of growth factors, adhesion molecules, and other chemical signals. It is far from understood exactly how these interact. It is clear that the cellular responses are greatly influenced not only by what chemicals are present but also by the context into which they are introduced. The action triggered by any of these mediators is influenced by other mediators in the environment, when the mediators are generated in relation to the wound healing process, and by what cells are targeted (Fig. 20-14).

## Pathologic Basis of Veterinary Disease, 4th Edition

### 20.1.4.2 UVEA

#### 20.1.4.2.1 Uveal Inflammation

The nomenclature of uveal inflammation is the same as that is used in clinical ophthalmology (Box 20-8). Hypopyon is the accumulation of neutrophils and fibrin that settles ventrally within the anterior chamber (Fig. 20-15). Inflammation within the iris and ciliary body is usually referred to as anterior uveitis, although iridocyclitis is equally accurate. Inflammation limited to the choroid is choroiditis; inflammation limited to the vitreous is hyalitis; inflammation throughout the uveal tract is panuveitis; and inflammation involving the uveal tract and the adjacent ocular cavities (anterior chamber, posterior chamber, and vitreous) is endophthalmitis. Inflammation that spreads to involve sclera is known as panophthalmitis. Although these terms are widely used in clinical ophthalmology, in reality the vascular tunic within the globe is a unified structure and virtually all examples of clinically significant uveal inflammation involve all portions of the uvea at least to some degree and have at least a little bit of effusion into the ocular chambers. Furthermore, the globe is a sealed sphere filled with fluid, so that inflammatory mediators or toxic products of infectious agents are likely to be widely disseminated within the globe. Thus from a purely histologic perspective, virtually all cases of uveitis can be correctly classified as endophthalmitis.

1365

1367

**Fig. 20-14 Schematic diagram of corneal wound healing.** The outcome of corneal wound healing depends in part on the balance among growth factors coming from the tear film, injured epithelium and stroma, and immigrating leukocytes. *EGF*, Epidermal growth factor; *FGF*, fibroblast growth factor; *HGF*, hepatocyte growth factor; *KGF*, keratocyte growth factor; *PDGF*, platelet-derived growth factor; *TGF- $\beta$* , transforming growth factor- $\beta$ ; *VEGF*, vascular endothelial growth factor.

## Pathologic Basis of Veterinary Disease, 4th Edition

20.1.4.2.1.1

### Box 20-8 Histologic-Clinical Correlation in Uveitis

The uveal tract responds to inflammatory stimuli as do other tissues. The macroscopic manifestations detectable by clinical examination are as follows:

- Aqueous flare: an increase in protein content within the aqueous humor increases light scattering
- Iris swelling and color change: iris stromal hyperemia, edema, and leukocyte accumulation
- Conjunctival reddening: hyperemia of the superficial and deep conjunctival blood vessels in response to vasoactive chemicals generated by the nearby uveitis
- Hypopyon: the accumulation of neutrophils and fibrin that settles ventrally within the anterior chamber
- Keratic precipitates: small clusters of macrophages and/or neutrophils adherent to the corneal endothelium
- Peripheral corneal midstromal vascularization: persistent inflammation results in the generation of enough angiogenic growth factors to stimulate “accidental” migration of limbal blood vessels into the peripheral cornea

Fig. 20-15 **Hypopyon (bilateral), feline infectious peritonitis, cat.** A mixture of fibrin and neutrophils is present within the anterior chamber of the eyes. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

A further source of confusion between histopathologic and clinical terminology is a consequence of identification of the predominant leukocyte in the exudate. As is true of lesions in many other tissues,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

histopathologic examination underestimates the number of rapidly migrating granulocytes and is misled by the gradual accumulation of nonemigrating mononuclear leukocytes. Neutrophils rapidly accumulate within the aqueous or vitreous humors where they can be detected by clinical or cytologic examination. Unless bound up in fibrin, those leukocytes are washed away during histologic processing, leaving only the predominantly mononuclear population within the uveal stroma. This is not unique to the globe: An identical opportunity for confusion exists in correlating cytologic and histologic lesions in immune-mediated joint disease, chronic rhinitis, and pyometra (among others).

20.1.4.2.2

### Causes of Uveitis

Uveitis can be initiated by a wide array of infections, immune responses, and trauma. Tissues of the globe usually act as an integrated unit, so injury to one part almost always has at least some influence on the health of other parts of the globe. The globe is filled with fluid, thereby allowing chemical messengers generated in one part of the globe to be absorbed by distant intraocular tissue. The iris stroma, in particular, is highly reactive because there is free communication between it and the aqueous humor. Any toxins, chemical mediators of inflammation, or growth factors secreted into the aqueous will be absorbed by the iris, causing that portion of the uveal tract to react. (See later discussion under Preiridal Fibrovascular Membrane).

Most of the infectious causes of uveitis are ocular responses to systemic viral, bacterial, or parasitic diseases in which the uveal tract is only one of many tissues affected. Endophthalmitis as the sole manifestation of infectious disease is usually seen only as a sequela to penetrating injuries or perforating ulcers that allow the entry of environmental organisms into the globe. There are no viral causes of endophthalmitis, although there are a few systemic viral infections that cause vasculitis or retinitis that result in a uveal inflammatory response. Aberrant migration of nematode or trematode larvae will occasionally cause endophthalmitis, as will ocular colonization by a variety of protozoal parasites that cause systemic disease (toxoplasmosis and encephalitozoon in particular). Uveal involvement in systemic mycoses and protothecosis is particularly common in animals in certain geographic regions.

Immune-mediated uveitis is a particularly frequent finding. In only a few types is there a reasonable understanding of the pathogenesis, as in uveodermatologic syndrome and phacoclastic uveitis (see later discussion). In the great majority, there is a chronic lymphocytic-plasmacytic endophthalmitis with no demonstrable infectious agent, and a moderately successful clinical response to immunosuppressive therapy (see Idiopathic Lymphonodular Uveitis later). The lesion is clearly the result of an immunologic response, but it is not known whether such a lesion reflects primary immune-mediated disease, or simply a response to an elusive infectious agent that has long since disappeared.

Ocular trauma is a frequent cause of transient endophthalmitis. The uvea will also respond to afferent neural signals and chemical factors released from an injured cornea, so that with any significant corneal ulceration or keratitis one can expect to have at least a mild anterior uveitis.

20.1.4.3

### IMMEDIATE RESPONSE TO INJURY: UVEITIS

Because the uveal tract has a fibrovascular stroma similar to the lamina propria of intestine or the dermis of skin, it undergoes all of the usual inflammatory reactions. There is nothing at all unique about these reactions. What is unique, however, is the importance of the consequences of that inflammation for other parts of the globe.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 20.1.5 DELAYED RESPONSES TO INJURY

What is most distinctive about uveitis is not the macroscopic or microscopic character of the inflammatory reaction itself, but the consequences of that inflammation for adjacent portions of the globe. These bystander effects, which include anterior and posterior synechiae, retinal detachment, cataract, corneal vascularization, preiridal fibrovascular membrane, and glaucoma, are clinically significant and are frequently the targets of therapeutic intervention.

1367

1368

**Fig. 20-16 Posterior synechia, pupillary block and iris bombé, eye, sagittal section, dog. A,** The iris has adhered to the lens, creating a pupillary block and subsequent iris bombé. Cloudy exudate fills the vitreous, and its accumulation in the subretinal space has caused complete retinal detachment. These changes occurred as a consequence of corneal perforation and secondary septic endophthalmitis. **B,** Same globe as Fig. 20-16, A. The serous effusion from the choroid has caused retinal detachment, which has serious implications for retinal survival. Additional lesions include posterior synechia, iris bombé, ciliary-lenticular adhesions, and circumferential cortical cataract. The combination of posterior synechia, pupillary block, iris bombé, and secondary peripheral anterior synechia is an exceedingly common sequence in the pathogenesis of glaucoma secondary to uveitis. H&E stain. (*A and B, Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

Synechiae are adhesions between the inflamed, sticky iris and either the lens or cornea. Adhesion to the anterior capsular surface of the lens (in the normal globe, the iris lies against the lens capsule) is known as posterior synechia. The adhesion is initially fibrinous but, if allowed to persist, will become a firm fibrous adhesion. If that adhesion is sufficiently extensive around the pupillary margin (i.e., approaching the full circumference of the pupil), there will be significant impairment of aqueous outflow from the posterior chamber to the anterior chamber (pupillary block) and inevitable secondary glaucoma. Increased pressure within the posterior chamber in the presence of a circumferential posterior synechia results in anterior bowing of the iris known as iris bombé (Fig. 20-16, A).

Anterior synechia is a focal-to-diffuse iridocorneal adhesion. Because the iris is not normally in proximity to the cornea, anterior synechia is much less prevalent than posterior synechia. It is most commonly seen as a sequela to iris prolapse, in which the flexible iris is literally “sucked up” into the corneal defect, where it then becomes anchored by fibrin and later by fibrosis. Peripheral anterior synechia commonly accompanies iris bombé and preiridal fibrovascular membranes (see later discussion).

Retinal detachment is a common sequela to uveitis and/or endophthalmitis by one of two mechanisms. Increased vascular permeability within the choroid results in effusion of fluid and cells into the subretinal space, resulting in so-called exudative detachment (Fig. 20-16, B). The normal retina is not actually adhered to the RPE. Fluid leaving the choroid during inflammation will preferentially accumulate in the potential space between the retina and RPE because its only alternative would be to try to escape through the dense fibrous shell of the sclera. Alternatively, replacement of fibrinous exudates by fibrous tissue within the vitreous may result in tractional detachment. The immediate and delayed visual consequences of retinal detachment are discussed later (see discussion on diseases of the retina). If there is a lot of fibrovascular ingrowth as a consequence of organization of vitreal exudate, the maturing fibrovascular tissue routinely creates a dense membrane across the anterior surface of the vitreous (just posterior to the lens). This cyclitic membrane is anchored into the ciliary epithelium, and often incorporates remnants of the detached retina.

1368

1369

**Fig. 20-17 Corneal endothelialitis, cornea, cat.** Neutrophils adhere to and have accumulated on and in the corneal endothelium. When numerous, they separate the corneal endothelial cells from the adjacent Descemet's membrane. This is a relatively frequent complication of anterior uveitis in cats and especially cats with feline infectious peritonitis. The leukocytes may be predominantly neutrophils or lymphocytes, depending on the pathogenesis and the duration of the uveitis. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Cataracts are frequent sequela to uveitis, but the exact mechanisms are poorly understood. We do know that the avascular lens is entirely dependent on the aqueous humor for the delivery of nutrients and the removal of metabolic waste products. In eyes with uveitis, there is a notable drop in the production of aqueous humor (ocular hypotension is one of the clinical features of uveitis), resulting in lens “malnutrition.” It is assumed that the lens is also susceptible to injury by mediators of inflammation and other toxic products in the aqueous humor of inflamed globes.

Corneal endothelialitis is characterized by an infiltration of neutrophils and/or lymphocytes into the corneal endothelium (Fig. 20-17). It usually is seen in globes with other lesions of chronic uveitis, but sometimes it is the most obvious histologic lesion of a uveitis that has almost disappeared (at least histologically) from other parts of the globe. It is much more prevalent in feline globes with feline infectious peritonitis (FIP) and idiopathic lymphonodular uveitis than in any others. Its pathogenesis is unknown. It was once a common lesion as a delayed sequela to vaccination with modified live vaccines containing canine adenovirus 1, and occasionally to canine adenoviral hepatitis. Complement-fixing antibodies against the virus were present within the endothelium as a result of a previous viral infection, resulting in attraction of neutrophils and subsequent bystander injury to the endothelium. If the endothelial damage was of sufficient magnitude, the result was the development of severe and sometimes permanent corneal edema, commonly referred to as “blue eye.”

*Preiridal fibrovascular membrane* refers to a layer of granulation tissue on the anterior surface of the iris. It is created by budding and migration of capillaries from the iris stroma and recruitment of fibroblasts as a routine response to cytokine mediators of wound healing (Fig. 20-18). It is no different from granulation tissue anywhere else in the body, but in typical ocular fashion, it achieves special significance within the globe. If the granulation tissue migrates across the anterior face of the lens, it creates a pupillary block resulting in secondary glaucoma. Alternatively, this granulation tissue can also migrate across the anterior face of the filtration angle to create a peripheral anterior synechia and once again cause secondary glaucoma (Fig. 20-19). Like any immature granulation tissue, it is also susceptible to hemorrhage and is a frequent cause of anterior chamber hemorrhage, known as hyphema. Wound healing following uveitis is only one of several mechanisms for the development of preiridal fibrovascular membranes, which are described in greater detail in the section on glaucoma.

1369

1370

**Fig. 20-18 Preiridal fibrovascular membrane, iris, dog.** A membrane formed by proliferating fibroblasts and capillaries has grown out from the iris stroma and has adhered to the anterior surface of the iris (represented here by the thin layer of pigmented melanocytes). These membranes form in response to growth factors within the aqueous humor, originating from such varied sources as intraocular neoplasms, or follow retinal detachment or chronic uveitis. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-19 Mature preiridal fibrovascular membrane, iris, dog.** A layer of mature granulation tissue has adhered to the anterior surface of the iris. Contraction of the maturing membrane has distorted the shape of the iris and has caused it to adhere to the posterior surface of the cornea (peripheral anterior synechia). If extensive, the anterior synechia will result in secondary glaucoma. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Midstromal corneal vascularization is an extremely common and clinically useful clue pointing to the presence of chronic uveitis. The vessels grow inwardly from the limbus. It has no known functional significance and appears to be a purely accidental lesion because the blood vessels of the limbus respond to angiogenic growth factors being produced within the globe as part of the ongoing inflammation and repair.

*Phthisis bulbi* refers to a shrunken, disorganized endstage globe. It is not a sequela only to uveitis, but severe uveitis is the most common cause.

### 20.1.5.1

#### LENS

The stereotypic histologic response of the lens to injury is hydropic swelling of the injured lens fibers, fiber disintegration resulting in cortical liquefaction, and abortive efforts at regeneration. This combination of changes is essentially identical, regardless of pathogenesis. They all result in opacification of the lens, referred to by the generic term “cataract.”

## Pathologic Basis of Veterinary Disease, 4th Edition

In clinical ophthalmology, cataracts are extensively subclassified by location within the lens, by age of onset, by the macroscopic appearance, or by the state of progression. This gives rise to an exceedingly complicated list of purely descriptive adjectives that are not at all reflective of the pathogenesis. Such classification is used mostly when dealing with inherited cataracts in dogs to ensure that the data being collected about the frequency or behavior of a cataract in a specific breed are indeed referring to the same disease.

The stereotypic microscopic changes of cataracts (Figs. 20-20 and 20-21) are various combinations of the following, listed in order of overall frequency:

1. Fragmentation and liquefaction of cortical fibers, creating spherical globules of denatured lens protein known as Morgagnian globules.
2. Hydropic swelling of cells, known as bladder cells, attempting but failing to regenerate
3. Hyperplasia and fibrous metaplasia of lens epithelium; the epithelial hyperplasia may create plaquelike thickening with or without fibroblastic metaplasia
4. Posterior lens epithelial migration; the lens epithelium migrates from the equator to lie under the posterior lens capsule; the normal adult lens has no epithelium posterior to the equator
5. More variable changes include lens swelling in acute cataracts, lens shrinking with wrinkling of the lens capsule in advanced ("hypermature") cataracts, and intralenticular mineralization

1370

1371

**Fig. 20-20 Cataract, lens, dog.** There is epithelial hyperplasia of the lens with fibroblastic metaplasia, formation of bladder cells (*arrows*), and a Morgagnian globule (*arrowhead*). H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-21 Anterior cortical cataract, lens, fish.** Note the lens epithelial proliferation, fibroblastic metaplasia, and prominent bladder cells. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The lens is capable of additional responses to injury other than those associated with cataracts, but these are much less frequent. As discussed in the section on phacoclastic uveitis, rupture of the lens capsule allows regenerative lens epithelium to escape from the lens, undergo fibroblastic metaplasia, and migrate within the anterior and posterior chambers, sometimes with devastating consequences. The same type of proliferation complicates cataract surgery, producing thick plaques of fibroblast-like epithelial cells that are aesthetically displeasing and reduce visual acuity.

### 20.1.5.2

#### RETINA AND VITREOUS

The general pathology of the retina resembles that of the brain. The neuronal elements of the adult retina of higher mammals do not regenerate; the outer segments of the photoreceptors, however, have a rapid turnover and have among the highest metabolic activity in the body. As long as the cell body within the outer nuclear layer remains viable, photoreceptors can be quickly regenerated.

The RPE remains mitotically active throughout life. Like other epithelia, it repairs itself, first by sliding viable cells into the area where cells have been lost and then by mitosis. Fibroblastic metaplasia is common (see later discussion).

The glial elements of the retina, particularly the astrocytes that reside within the inner nuclear layer (Müller cells), are exceedingly hardy and capable of proliferation. Repair of most cases of retinal necrosis occurs primarily by proliferation of Müller cells, which eventually form a dense glial scar, sometimes with a

## Pathologic Basis of Veterinary Disease, 4th Edition

contribution from migrating RPE cells that can also undergo fibroblastic metaplasia (Fig. 20-22). Occasionally the astrocytes proliferate along the vitreal face of the retina, forming a preretinal fibroglial membrane. Subretinal membranes (between the photoreceptors and the RPE) of a similar microscopic appearance are seen with chronic detachments and originate from migrating Müller cells or from retinal pigment epithelium that has undergone fibroblastic metaplasia.

**Fig. 20-22 Retinal atrophy (advanced), retina, dog.** There is virtually complete loss of all retinal layers, including photoreceptors, leaving only a few surviving blood vessels and glial cells. The impression of retinal fibrosis is mostly the result of fibrous astrocytosis originating within the inner nuclear layer. This lesion could be the end stage of almost any severe retinitis or retinal necrosis (including retinal detachment, retinal hypertension, glaucoma, or trauma). C, choroid; S, sclera. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The vast majority of retinal lesions fall into three categories:

1. Inflammation as a result of extension from endophthalmitis or encephalitis. Inflammation targeting the retina specifically is exceedingly uncommon. The character of the inflammation within the retina is exactly the same as it is within the brain: neuronal necrosis, perivascular cuffing, and gliosis. What is different about the retina, however, is its susceptibility to exudative retinal detachment. Fluid and cells escaping from inflamed retinal vessels are most likely to accumulate in the subretinal space and result in the separation of the photoreceptors from the RPE and the choroidal vasculature (Fig. 20-23). The photoreceptors are therefore likely to become necrotic, not only from the by-products of inflammation, but from ischemia and other forms of malnutrition resulting from their anatomic dislocation from the RPE (remember that the photoreceptors are entirely dependent on their intimate contact with the RPE and their proximity to the choroid for their nutrition). Serious photoreceptor damage will occur within days.

2. Noninflammatory photoreceptor degeneration from inherited metabolic disease, retinal detachment, or toxicity. Histologically, almost all of these photoreceptor diseases are indistinguishable from one

1371

1372

## Pathologic Basis of Veterinary Disease, 4th Edition

another. The changes are the same regardless of whether the damage is from inborn metabolic errors (especially the innumerable inherited photoreceptor dysplasias of purebred dogs), excessive exposure to light or other radiation, or to toxic chemicals.

3. Destruction of the neural elements of the inner retina (nerve fiber layer, ganglion cells, and inner nuclear layer) as a result of glaucoma. The pathogenesis of the inner retinal destruction, and destruction of the optic nerve, remains a source of great controversy and probably varies among species and with the type of glaucoma. Some of the damage is probably from pressure-induced collapse of retinal and even choroidal blood vessels, and some is probably the result of pressure-induced interference with the axoplasmic flow of nutrients within the optic nerve and nerve fiber layer (see Glaucoma section).

**Fig. 20-23 Retinitis, retinal necrosis (with exudative retinal detachment), cryptococcosis, retina, dog.** *Cryptococcus neoformans* organisms are numerous within the subretinal exudate. A mixture of fibrin, leukocytes, and organisms has replaced a portion of retina and created a focal preretinal exudate. Periodic acid–Schiff reaction. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.1.5.2.1

### Retinal Detachment

The neurosensory retina (not including the RPE) is physically anchored only at the ora ciliaris and at the optic disc. It is held in apposition to the RPE partly by the physical presence of the gel-like vitreous and partially by the membrane forces related to the intricate interdigitations between photoreceptors and surface crevices in the RPE. The potential space between the photoreceptors and the RPE is the remnant of the lumen of the primary optic vesicle, and it persists throughout life. Retinal detachment (sometimes referred to as retinal separation by those who correctly point out that the retina is never really attached at all) is a frequent and serious complication of many different ocular diseases. It may be focal or more diffuse. The distance of separation between the photoreceptors and the RPE may only be slight (so-called flat detachments) or the entire retina may be separated and suspended in the vitreous (Fig. 20-24)

## Pathologic Basis of Veterinary Disease, 4th Edition

supported only by its durable attachments to the ciliary body and optic nerve (so-called morning glory detachment because of its resemblance to a tubular flower when viewed by clinical examination through the pupil).

The most frequent types of retinal detachment are as follows:

1. Exudative retinal detachment: accumulation of serous, fibrinous, or cellular exudates (or hemorrhage) within the subretinal space as a consequence of choroiditis, retinitis, or retinal vascular hypertension (Fig. 20-25; also Figs. 20-34 and 20-36).
2. Rhegmatogenous retinal detachment: leakage of liquefied vitreous into the subretinal space through traumatic or degenerative breaks in the peripheral retina. This may occur secondary to trauma or to a very frequent aging lesion known as microcystoid peripheral retinal degeneration.
3. Tractional retinal detachment: maturation of hemorrhage or fibrin within the vitreous, which pulls the retina away from the choroid. As it matures, the combination of fibrous tissue, fibrin, and detached retina lies as a membrane stretching from ciliary body to ciliary body across the posterior surface of the lens, a lesion known as a cyclitic membrane.

**Fig. 20-24 Retinal detachment (complete), globe, sagittal section, dog.** Serous effusion from the growth of metastatic lymphoma (L) within the choroid and subretinal space has caused a complete retinal detachment. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-25 Retinal detachment (traumatic), globe, sagittal section, dog.** The detachment has been caused by accumulation of subretinal hemorrhage. The retina remains attached only at the sites of true anatomic attachment: the optic disc and its junction with the pars plana of the ciliary body. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

1372

Retinal detachment is immediately significant because the image on the retina is out of focus, but more serious is the rapidity with which the photoreceptors are damaged. The outer segments of the photoreceptors, responsible for light absorption and electrical signal generation, are lost within 2 weeks following experimental saline-induced flat detachment (Fig. 20-26). Histologic and clinical evidence in natural disease suggests that this degeneration occurs much more rapidly (a few days at most) in the presence of toxic by-products of inflammation, or when the distance between the retina and the RPE is great. The inner segments of the photoreceptors and the cell bodies within the outer nuclear layer are much more resistant to injury and may remain viable for months (Fig. 20-27).

1373

The retinal consequences of detachment probably vary by species, depending on how much intrinsic retinal vasculature is present. There is virtually no published information, but the almost avascular retina of horses should be much more susceptible to full-thickness ischemic injury than the well-vascularized retinas of dogs or cats (in which the inner half of the retina remains unaffected by detachment).

The detached retina in every species produces a variety of angiogenic growth factors presumably intended to increase its own blood supply. In species other than primates, however, there is a little evidence of stimulation of retinal angiogenesis. Instead, these growth factors percolate through the vitreous and are absorbed into the iris stroma where they stimulate the production of a preiridal fibrovascular membrane. The result is a substantial risk of secondary glaucoma from either pupillary block or occlusion of the filtration angle (see under Glaucoma).

## Pathologic Basis of Veterinary Disease, 4th Edition

### 20.1.5.3 EYELIDS, CONJUNCTIVA, AND ORBIT

#### 20.1.5.3.1 Eyelids

The responses of the eyelids to injury, the spectrum of potentially injurious agents, and the susceptibility to neoplasia are exactly the same as for skin and will not be discussed further.

Although the responses of the eyelid itself to injury may be identical to those of skin elsewhere, there may be unique consequences for other parts of the globe, particularly the nearby conjunctiva and cornea. There may be direct spread of inflammation or neoplasia from the eyelid to the nearby conjunctiva or even to the cornea. Physical distortion of the eyelid from inflammation, scarring, or neoplasia may interfere with the ability of the eyelid to distribute the tear film, or to properly protect the cornea from injury. The abnormal eyelid may even cause mechanical injury by scraping the cornea that it was designed to protect.

There are only a few inflammatory diseases and neoplasms with a predilection for the eyelids, and these are discussed later under specific diseases. It is appropriate to be skeptical when attempting to prove an infectious cause for blepharitis in any species. There is a tendency to assume that whatever infectious agents are isolated from swabs of the eyelid margin or from expressed Meibomian secretion must be the cause of the blepharitis. This is flawed logic because ordinarily those same organisms are readily isolated from the conjunctival sac, or the eyelid margin, of perfectly healthy animals.

**Fig. 20-26** *Retinal detachment (serous), retina, dog.* Floccular eosinophilic debris (D), the histologic counterpart of a serous exudate, has pushed the retina away from the retinal pigment epithelium (RPE). There is hypertrophy (arrows) of the RPE, degeneration of the photoreceptors, and focal loss of neurons from the outer nuclear layer. RPE hypertrophy occurs after just a few hours of detachment. The rapidity of progression of the photoreceptor degeneration depends on the magnitude of the detachment and the toxicity of the fluid within the subretinal space. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-27 Retinal detachment (chronic), retina, dog.** There is hypertrophy of the retinal pigment epithelium (*arrows*), with loss of nuclei from the outer nuclear layer as well as disintegration of the photoreceptors. At this stage, the loss of vision from this portion of retina is irreversible. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

1373

20.1.5.3.2

### Conjunctiva

1374

The reaction of conjunctiva to injury is the same as that of any other mucous membrane. It has a narrow spectrum of responses to injury and only seldom can an etiologic diagnosis be made by histologic examination of a conjunctival biopsy. The epithelium responds to acute injury with ulceration. With chronic mild injury, there is squamous metaplasia. In animals with pigmented conjunctivae, chronic irritation also stimulates hyperpigmentation, just as it often does in skin. If there is desiccation, the areas of squamous metaplasia will often be keratinized.

The underlying lamina propria usually responds with a stereotypic lymphocytic-plasmacytic accumulation, with the development of hyperplastic lymphoid nodules if the stimulation is persistent. Neutrophils are seldom numerous within the tissue; if present at all, they are usually found migrating through the epithelium en route to the conjunctival sac where they will do battle with the infectious agents that might be present as opportunistic pathogens. Eosinophils are occasionally present in poorly defined allergic conjunctivitis in dogs, cats, and horses. They are present in greater numbers in the more discrete collagenolytic granulomas in horses with habronemiasis.

Looking for specific infectious agents in sections of conjunctiva is usually a waste of time. It is true that some of the viral diseases and chlamydial infections can leave specific footprints in the form of inclusion bodies, but these are usually present only very early in the course of these diseases, at a time before the lesion is assessed by conjunctival scraping or biopsy examination.

### 20.1.5.3.3 Orbit

There is nothing specific about the reaction of orbital tissues to injury. Each constituent (bone, fat, and muscle) reacts to injury in an identical fashion to that in the same type of tissue elsewhere. As has been a recurring theme in discussions of diseases in other parts of the globe and ocular adnexa, an event at one site almost always causes significant consequences for other parts of the globe, such as the following:

1. Accumulation of fluid, cellular exudates, or tumor cells in the orbit, resulting in protrusion of the globe (exophthalmus) with the resulting risk of corneal ulceration secondary to desiccation
2. Destruction of orbital tissue and loss of fat from emaciation having the opposite effect; the globe sinks into the orbit, creating the risk of secondary entropion and resultant corneal irritation
3. Injury to extraocular muscles, resulting in abnormal positioning of the globe, thus predisposing the cornea to ulceration from eyelid trauma or desiccation
4. Significant damage to the function of the lacrimal gland, resulting in injury to the cornea via desiccation
5. Space-occupying orbital lesions, particularly neoplasms, which may cause injury to the optic nerve and result in blindness

## 20.2 DISEASES OF THE EYE, EYELID, CONJUNCTIVA, AND ORBIT

### 20.2.1 ANOMALIES OF THE GLOBE AS A WHOLE

The globe has a complex embryogenesis involving carefully orchestrated interactions of neur ectoderm, surface ectoderm, and periocular mesenchyme throughout embryogenesis and in carnivores into the fifth or sixth the week after birth. The opportunity for developmental error is thus substantial. This also means that, especially in carnivores, all developmental errors are not necessarily congenital. Because the globe is not essential for postnatal survival, even severe anomalies are encountered with considerable frequency. Selective breeding practices have increased the frequency of ocular anomalies. Those that are important or prevalent will be discussed in sections dealing with diseases of the specific ocular segment affected.

As a general framework for understanding ocular anomalies, they are most conveniently divided into failures of initial induction, failures in remodeling, and late failures in atrophy. Included in this section are only those anomalies in very early induction that affect the eye as a whole. Those lesser anomalies that result from later defects in remodeling or atrophy are discussed in the sections devoted to diseases of the most severely affected components of the eye.

The eye begins very early in gestation as an outgrowth from the primitive forebrain. This primary optic vesicle grows outwardly from the brain toward the overlying surface ectoderm, remaining connected to the brain by the optic stalk. As the primary optic vesicle approaches the overlying ectoderm, it induces a focal thickening in that ectoderm, known as the lens placode. That placode thickens, separates from the surface ectoderm, and migrates inwardly to indent the spherical optic vesicle. As the lens pushes into that optic vesicle, the vesicle collapses upon itself to form a bilayer optic cup ([Fig. 20-28](#)). When the lens vesicle separates from the surface ectoderm, that ectoderm re-forms over the lens and forms the presumptive corneal epithelium. The presence of

## Pathologic Basis of Veterinary Disease, 4th Edition

the epithelium seems to act as a magnet to attract one or more waves of periocular mesenchyme that will form the primitive corneal stroma and endothelium. This periocular mesenchyme is derived from the neural crest, and eventually will also form the sclera, uveal stroma, and a well-developed but transient intraocular network of blood vessels (hyaloid artery and tunica vasculosa lentis) that nourish the developing retina and lens (Fig. 20-29). The eyelids, extraocular muscles, lacrimal gland, and orbit are formed more or less independent of the globe and are generally not affected by those diseases that impair development of the eye itself.

1374

1375

**Fig. 20-28 Schematic diagram of the formation of the primary optic vesicle and optic cup.** Note that the optic fissure is present because the optic cup is not yet fused inferiorly. **A**, Formation of lens vesicle and optic cup with inferior choroidal or optic fissure. Mesenchyme surrounds the invaginating lens vesicle. **B**, Surface ectoderm forms the lens vesicle with a hollow interior. Note that the optic cup and optic stalk are of surface ectoderm origin. RPE, Retinal pigment epithelium. (*A and B*, From Cook CS, Sulik K, Wright K: *Embryology*. In Wright KW, ed: *Pediatric ophthalmology and strabismus*, St Louis, 1995, Mosby.)

Anophthalmia is a very rare condition in which there is no detectable development even of the primary optic vesicle. It is usually bilateral. The vast majority of the cases clinically diagnosed as “anophthalmia” are in fact severe microphthalmia, and some vestige of a globe is found somewhere within the orbit.

Microphthalmia is the presence of a miniature, disorganized globe in an orbit of relatively normal size. In the great majority of cases, the anomaly does not reflect a primary maldevelopment but rather involution following some type of exogenous injury to a globe that up to that stage was normal in its development. This includes in utero trauma, ischemic injury, and infection. Such globes can be remarkably small; usually it is a tiny pigmented nodule somewhere within the abundant fat and muscle still present within the orbit (Fig. 20-30). Microscopically the most durable and therefore the most recognizable remnants of the previously normal globe are the pigmented ciliary processes. If they are present, then one can be sure that the globe had reached a reasonably advanced state of embryologic development before undergoing regression.

Congenital cystic eye results from the failure of the primary optic vesicle to invaginate under the influence of the developing lens.

## Pathologic Basis of Veterinary Disease, 4th Edition

Cyclopia and synophthalmia are perceived clinically as a single midline globe, and virtually always occur in animals with other major developmental anomalies. They reflect failure of division of the very primitive optic primordium into paired symmetric optic stalks and vesicles (or perhaps subsequent fusion), which therefore results in a single midline globe. Most examples have some degree of duplication of intraocular structures, such as the retina or lens, and are properly termed synophthalmia (Fig. 20-31). As naturally occurring developmental anomalies, cyclopia and/or synophthalmia are exceedingly rare. However, ewes grazing pastures of the alpine legume *Veratrum californicum* on day 15 of gestation will give birth to lambs with this malformation. Ingestion of the plant before day 15 results in fetal death but no anomalies. Ingestion after day 15 results in various skeletal anomalies and cleft palate, but the globes are apparently normal. Similar ocular lesions have been experimentally induced in goats and cattle.

1375

1376

**Fig. 20-29 Fetal globe, gestational age day 34, dog.** The periocular mesenchyme is organizing to form the choroid and sclera. The anterior chamber has been formed, but the anterior lip of the optic cup has not yet folded inwardly to induce the formation of the iris and ciliary body. The relatively large lens is surrounded by a rich vascular tunic derived from the hyaloid artery and pupillary membrane. RPE, Retinal pigment epithelium. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-30 Microphthalmia, globe and orbit, calf.** Note that the orbit (*right*) remains relatively normal, probably indicating that the initial development of the globe was normal and that its current small size (*on the scalpel blade, left*) is a result of in utero injury and subsequent atrophy (indicating so-called secondary microphthalmia rather than a primary failure of ocular development). (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

Coloboma is the least severe of the developmental abnormalities affecting the globe as a whole. When used in this context, the word refers to a defect in the closure of the optic fissure, which is a normal channel in the floor of the optic cup that remains open long enough to allow the entry of the blood vessels that form the hyaloid artery and the perilenticular vascular tunic. This fissure normally closes in the last third of gestation, persisting longest near the posterior pole of the globe just ventral to the optic disc. If it persists for too long, there is the possibility that the developing retina will accidentally grow outwardly through this defect (i.e., coloboma) to cause a retrobulbar cyst lined by retinal neurectoderm (Fig. 20-32). This is a lesion made famous by its occurrence as one of the hallmarks of collie eye anomaly. The same defect occurs sporadically in other breeds of dogs and in horses, cattle, and cats. In Charolais cattle, colobomas at or near the optic disc are inherited as an autosomal dominant trait with incomplete penetrance.

The stepwise closure of the optic fissure appears to be orchestrated by soluble factors released from the retinal pigmented epithelium, which is developing from the neurectoderm of the posterior layer of the primitive optic cup. Because such colobomas are most commonly found in color-dilute animals, we assume that the proper chemical signaling is somehow related to the proper acquisition of pigment (or pigment-producing capability) by this neurectoderm (see later under Choroidal Hypoplasia).

1376

1377

**Fig. 20-31 Synophthalmia, globe, calf.** **A**, This fused globe has two lenses, two corneas, and partial duplication of the retina. **B**, Horizontal section of the fused globe revealing two lenses but a shared fused midline retina. (***A** and **B**, Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

**Fig. 20-32 Posterior polar coloboma, collie eye anomaly, globe, sagittal section, dog.** Failure of closure of the most posterior portion of the optic fissure has allowed outpouching of the developing retina, adjacent to the optic nerve. The protruding retina is covered by sclera. This result has prevented proper local formation of choroid and sclera, resulting in so-called scleral ectasia. Such globes always have choroidal hypoplasia. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

### 20.2.2 DISEASES OF THE GLOBE AS A WHOLE

#### 20.2.2.1 GLAUCOMA

Glaucoma is not a single disease but a group of diseases sharing specific physiologic and structural characteristics. It is a clinical syndrome characterized by a sustained increase in intraocular fluid pressure that is detrimental to the health of the optic nerve and the retina, resulting in loss of vision and eventual blindness. Glaucoma causes changes in virtually every tissue within the globe, but changes in the retina and optic nerve are the most important. The syndrome is most prevalent in dogs, followed by cats and horses. It is rarely documented in other species but undoubtedly exists in all. Glaucoma is extremely prevalent as a cause for ocular pain and blindness in dogs, and it is by far the leading reason for surgical removal of the globe (enucleation). It is relatively less common in cats, yet it is still the leading cause for enucleation in that species. Its frequency in horses may be greatly underestimated because of its variable clinical presentation in that species and because ocular pressure is not routinely measured in horses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Theoretically, glaucoma may result from an increase in the production of aqueous humor or a decrease in its removal. In practical terms, however, all examples of glaucoma in domestic animals result from impairment of aqueous outflow. Glaucoma is usually divided into primary and secondary glaucoma. *Primary glaucoma* refers to those examples occurring without any known acquired intraocular disease to explain the increase in pressure. The great majority of these result from developmental errors in the structure and function of the aqueous drainage pathways. Secondary glaucoma refers to those examples in which there are changes such as lens luxation, pupillary block, or intraocular neoplasia to explain the impairment of aqueous humor outflow.

The aqueous humor that fills the anterior and posterior chambers is a low-protein transparent fluid just slightly denser than water. It is formed continuously by a combination of plasma filtration and active secretion by ciliary epithelium. Its chemical composition varies somewhat among species, but it always has a very low total protein concentration (about 5% of total plasma protein) but an amino acid concentration 50% higher than that of plasma. It contains glucose and electrolytes in concentrations roughly equivalent to those in plasma. The aqueous humor produced within the ciliary body circulates past the lens to provide nutrients to it and remove waste products, enters the anterior chamber through the pupil, circulates within the anterior chamber to nourish corneal endothelium and stroma, and then exits through slitlike spaces at the junction between peripheral cornea and iris. This iridocorneal angle extends circumferentially around the globe and normally has tremendous reserve capacity to accommodate fluctuations in aqueous production and to provide a substantial margin of safety against the development of glaucoma secondary to partial blockage of the aqueous outflow by accumulations of blood or inflammatory debris.

The maintenance of intraocular fluid pressure is a balance between aqueous production and outflow and in domestic animals is influenced primarily by resistance to outflow. The rate of production varies from 2.5  $\mu$ l per minute in dogs to 15  $\mu$ l per minute in cats. The outflow pathway is through the iridocorneal angle and more specifically through a series of perforations in the connective tissue of the peripheral cornea, sclera, and iris stroma that makes up the trabecular meshwork. The microscopic anatomy of this outflow pathway varies by species, but all examples are quite similar in general design.

The trabecular meshwork is a series of mesenchymal sieves that occupies the iridocorneal angle and extends circumferentially around the globe. Embryologically the trabecular meshwork is formed by rarefaction of the same mesenchyme that forms iris stroma. In carnivores this remodeling continues for several weeks after birth (Fig. 20-33). This area of perforated mesenchyme is referred to as the ciliary cleft. It is bordered externally by sclera, posteriorly by the muscles of the ciliary body, and internally by the iris stroma. Its anterior border, separating it from the anterior chamber, is formed by the pectinate ligament. With proper instrumentation (gonioscopy), the pectinate ligament is visible through the cornea as a series of cobweblike branching cords (carnivores) or a fenestrated sheet (ungulates), stretching from the termination of Descemet's membrane to the anterior portion of the iris root (Fig. 20-34).

1377

1378

**Fig. 20-33 Normal neonatal globe, immature ciliary cleft, trabecular meshwork and iris stroma, dog.** The trabecular meshwork will develop by rarefaction and remodeling of this ciliary cleft over a period of a few weeks during normal maturation. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-34 Normal adult ciliary cleft, trabecular meshwork and other portions of the drainage pathway, cat.** The arrows indicate the predominant pathway for aqueous outflow in carnivores. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Ultrastructurally the trabecular meshwork is a series of connective tissue beams covered (completely or incompletely, depending on the species) by a single layer of trabecular endothelial cells connected to each other by delicate cytoplasmic tendrils. The cells are phagocytic and are probably important in regulating the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

outflow of aqueous humor. Most of that flow is probably by transcellular movement of pinocytotic vesicles across the cytoplasm of the trabecular endothelium.

In most species, the most functionally significant portion of the trabecular meshwork exists in the deep peripheral corneal stroma and inner sclera, and is known as the corneoscleral meshwork. Aqueous humor passing through this portion of the meshwork then enters a network of large veins, known as the scleral venous plexus, which is embedded in the peripheral sclera. The aqueous humor entering these veins will then be returned to the systemic circulation. A small percentage of the aqueous humor entering the filtration angle will exit via a more posterior route known as the uveoscleral meshwork, percolating into the veins of the ciliary body and choroid rather than into the scleral venous plexus (Fig. 20-34). The proportion of aqueous humor leaving the globe by this more posterior route varies by species: 3% in cats, 15% in dogs, and a larger (but undetermined) percentage in horses. Differences in the proportion of fluid leaving the globe by different routes might explain differing susceptibilities to different types of glaucoma among the domestic animals, and it also creates at least the potential for different types of therapeutic interventions.

20.2.2.1.1

### Box 20-9 The Most Frequent Histologic Lesions in Glaucoma

Atrophy of the nerve fiber layer and ganglion cell layer of the retina

Loss of neurons from the inner nuclear layer

Collapse of the trabecular meshwork

Corneal edema

Cataracts

Optic nerve atrophy

Optic disc cupping

Atrophy of ciliary processes

Corneal striae

These outflow pathways are not just passive conduits through which the aqueous humor can flow. There is an important physiologic resistance to outflow responsible for the maintenance of normal intraocular pressure. The exact anatomic and physiologic constituents of this outflow resistance remain incompletely defined but include important contributions from the endothelial cells lining the collagen beams within the trabecular meshwork, the glycosaminoglycans embedded in the matrix supporting those endothelial cells, and blood pressure within the scleral venous plexus.

## Pathologic Basis of Veterinary Disease, 4th Edition

The clinical (macroscopic) lesions of glaucoma are related to the secondary effects of increased pressure on various components of the globe. Although the increase in pressure is the result of obstruction of outflow in the anterior chamber, the pressure elevation is distributed throughout the fluid medium of the globe, and the effects are thus felt by all parts of the globe. These effects are the same, regardless of the pathogenesis of the glaucoma, and they vary with the rapidity of onset, the magnitude of the pressure elevation, and the duration of the elevation. They are also influenced by the age of the patient and by the species. The most obvious of the macroscopic changes include ocular enlargement, corneal cloudiness because of edema, pupillary dilation, and excavation of the optic disc. The most frequent microscopic changes in glaucoma are listed in [Box 20-9](#).

20.2.2.1.2

### Morphologic Changes Secondary to Glaucoma

*Buphthalmos* (megaloglobus) is stretching of the globe secondary to increased intraocular pressure. It is most obvious in dogs and least obvious in horses ([Fig. 20-35](#)). Histologically the sclera becomes thin, and the anterior chamber increases in its anterior-posterior dimension. The enlargement is significant because it probably causes pain, and it prevents the eyelids from closing over the cornea, thus resulting in corneal desiccation, which can lead to either corneal cutaneous metaplasia or ulceration (depending on the speed of onset and the severity of the desiccation).

1378

1379

**Fig. 20-35 Bilateral primary glaucoma (inherited), eye, rabbit.** The eyes are protruding and have diffuse gray corneal opacity typical of edema. Distinguishing ocular enlargement caused by glaucoma from exophthalmos caused by a retrobulbar mass is based on clinical assessment of intraocular pressure, the ability to push the globe more deeply into the orbit (retropulsion), and the presence or absence of an orbital mass as detected by radiography or other imaging techniques. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Corneal edema develops when the aqueous pressure exceeds the ability of the sodium pump within the corneal endothelium (in dogs, at about 40 mm Hg). More severe corneal edema then develops as a result of pressure-induced injury to that endothelium, and that injury may become permanent if the endothelial injury is so extensive that it exceeds the capacity of the corneal endothelium to repair itself by sliding, usually when there is a loss of more than 50% of corneal endothelial cells. Corneal edema secondary to glaucoma is much more frequent in dogs than in cats for reasons that remain unclear.

Corneal striae are breaks in Descemet's membrane occurring secondary to corneal stretching. They are visible on clinical examination as serpentine tracts of deep corneal stromal opacity.

Atrophy of the iris and ciliary processes occurs late in the course of glaucoma, probably as a consequence of chronic pressure-induced ischemia. Atrophy of the iris causes the initial physiologic pupillary dilation typical of glaucoma to become permanent. Atrophy of the ciliary processes eventually leads to normalization of intraocular pressure and even eventual hypotony, seen as part of very endstage glaucoma.

Cataracts are common in glaucoma, presumably as result of the stagnation of aqueous flow that results in inadequate delivery of nutrients to, and impaired removal of, metabolic waste products from the lens.

Lens luxation probably results from stretching of the zonules secondary to ocular enlargement. Pressure-induced degenerative change in the zonules is another possibility. The luxation may be into the anterior chamber or into the posterior chamber. Luxation into the posterior chamber requires that the vitreous has already liquefied. Such vitreal liquefaction is a common sequela to inflammation that may have preceded the glaucoma, and it also occurs as a sequela to the glaucoma itself. In globes with vitreal liquefaction, whether the dislocated lens moves anteriorly or posteriorly seems to be just a matter of chance.

Retinal degeneration is the most important secondary change in glaucoma and is the one against which most therapeutic efforts are directed. It is very important because it causes blindness as a result of damage to the ganglion cells, which cannot regenerate, even if the glaucoma is eventually brought under control. The exact pathogenesis for the characteristic retinal and optic nerve changes probably varies among species and among different types of glaucoma. At least some of the contributing factors include the following:

1. Pressure-induced ischemic damage following collapse of blood vessels in the retina, optic nerve, or choroid in response to increased pressure in the vitreous
2. Interference with ganglion cell nutrition by impairment of axoplasmic flow caused by pressure-induced compression of the axons passing through the lamina cribrosa
3. Direct damage to ganglion cells by elevated local production of excitatory amino acids, notably glutamate, from injured optic nerve and retina

The degeneration characteristically causes atrophy of the nerve fiber layer and ganglion cells, and later loss of neurons from the inner nuclear layer. The hardy astrocytes within the inner nuclear layer (Müller cells) remain intact. In classic glaucomatous retinal atrophy, the outer nuclear layer and photoreceptors remain unaffected for years (Fig. 20-36). This pattern of "inner retinal atrophy" with sparing of the outer nuclear layer and photoreceptors is virtually unique to glaucoma (remembering that inherited, nutritional and toxic retinopathies all target photoreceptors). In dogs with high-pressure glaucoma, however, it is

## Pathologic Basis of Veterinary Disease, 4th Edition

common to also see destruction even of outer portions of the retina. Such destruction sometimes occurs quite quickly, presumably in response to pressure-induced collapse of the superficial choroidal blood vessels (choriocapillaris) responsible for the nutrition of the photoreceptors and outer nuclear layer. In such cases, there is also necrosis of RPE.

1379

1380

**Fig. 20-36 Retinal atrophy, glaucoma, retina, horse.** There is loss of density in the nerve fiber layer and loss of virtually all the ganglion cells (*top*), but excellent preservation of the outer nuclear layer and photoreceptors. Retinal microscopic changes in glaucoma vary with its severity and duration and with the species affected. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-37 Cupping of the optic disc, galucoma, eye, dog.** The exact pathogenesis for the cupping in response to increased intraocular pressure probably involves many mechanisms and varies from species to species and among the different types of glaucoma. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Optic nerve changes are among the most controversial lesions seen in glaucoma. Much of the controversy centers around whether the optic nerve changes are just a consequence of glaucoma, or whether they can occur independently of the pressure changes. The answer probably varies with the species and with the type of glaucoma under consideration. The situation is greatly confused by incautious extrapolation of the results from human glaucoma research. Glaucoma in human beings is substantially different from that seen in most of our domestic animals. Microscopic changes in the optic nerve include degeneration of axons (Wallerian degeneration) and astrogliosis secondary to the loss of the ganglion cells, and pressure-induced posterior displacement of the lamina cribrosa. Optic disc cupping is almost pathognomonic for glaucoma. It may occur very quickly as a result of pressure-induced posterior displacement of the lamina cribrosa, or more slowly as a result of atrophy of the optic nerve itself from the loss of axons ([Fig. 20-37](#)).

### 20.2.2.1.3 The Classification of Glaucoma

#### 20.2.2.1.3.1 Primary glaucoma

Primary glaucomas are those glaucomas occurring without any significant contribution from disease elsewhere within the globe. Primary glaucomas are subdivided into those cases where there is detectable maldevelopment of the trabecular meshwork (goniodysgenesis), and those cases in which there are no primary histologic lesions (open-angle glaucoma). A very small proportion of these are truly congenital glaucomas in which clinical signs of glaucoma are evident in the first few weeks of life. The vast majority, however, have no clinically detectable increase in pressure or clinical signs related to glaucoma until middle-age or even older. The reasons for this delay in clinical onset are unknown.

#### 20.2.2.1.3.1.1 Goniodysgenesis.

Goniodysgenesis is a general term denoting imperfect development of the trabecular meshwork. It reflects incomplete remodeling of the solid mass of anterior chamber mesenchyme that gives rise to the stroma of the cornea and anterior uvea. In carnivores, most of this remodeling occurs in the first few weeks of life and involves rarefaction of what was previously a solid mesenchymal mass. In truly congenital glaucoma, there may be virtually no rarefaction (so-called trabecular hypoplasia), but in the great majority of cases there is reasonably complete development of the trabecular meshwork and other portions of the drainage system. The most common histologic anomaly is failure of the most anterior portion of the trabecular meshwork to be adequately remodeled, resulting in what looks like an abnormal solid or imperforate pectinate ligament ([Figs. 20-38 and 20-39](#)). The great majority occur as inherited disease in purebred dogs, with at least 20 different breeds known to be affected. The correlation between the severity of the goniodysgenesis and the frequency of glaucoma varies among breeds. It is sometimes quite poor, suggesting that there are other factors, perhaps functional rather than morphologic, involved in the pathogenesis of glaucoma.

The reasons for the delay in the onset of clinical signs of glaucoma, often for 5 years or more, are poorly understood. There may be age-related changes in the composition of trabecular meshwork matrix components or in lens position that result in a small decrease in aqueous outflow. Such minor decreases would normally be insignificant, but they may be critical to a dog that already has impaired aqueous drainage. Alternatively, acquired changes, such as preiridal fibrovascular

1380

1381

## Pathologic Basis of Veterinary Disease, 4th Edition

membrane or minor cellular infiltrates associated with a normally insignificant uveitis, might provide the “final straw” that triggers glaucoma in these predisposed individuals. There is no reason to presume that the triggering events are the same in each individual.

Fig. 20-38 **Goniodysgenesis, primary glaucoma, dog.** Note the absence of a normal pectinate ligament. Descemet's membrane (*right*) inserts directly into a broad band of stroma (*arrow*) continuous with the iris stroma. The rest of the trabecular meshwork is microscopically normal. Periodic acid–Schiff reaction. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Fig. 20-39 **Goniodysgenesis, primary glaucoma, dog.** Note the almost complete hypoplasia of the trabecular meshwork, the result of a profound arrest in remodeling of the mesenchyme within the ciliary cleft. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

### Primary open-angle glaucoma.

Some examples of primary glaucoma in dogs, cats, and horses occur in globes in which there is no visible abnormality in the structure of the trabecular meshwork or other portions of the aqueous outflow pathways. The best known is open-angle glaucoma in beagles. It has been widely used as a laboratory model, but its frequency outside of the laboratory appears to be very low. These dogs develop increased intraocular pressure by about a year of age, but usually do not have clinical signs of glaucoma (such as conjunctival congestion, corneal edema, and pupillary dilation) until they are between 2 and 4 years of age. In the early stages of glaucoma, all portions of the aqueous outflow pathways are histologically and ultrastructurally normal.

**Fig. 20-40 Secondary glaucoma (from posterior synechia), iris bombé and peripheral anterior synechia, globe, sagittal section, dog.** The original injury was a penetrating wound of the cornea that caused phacoclastic uveitis. The inflamed iris adhered to the ruptured lens, causing a pupillary block and then iris bombé. The anterior displacement of the iris resulted in narrowing of the iridocorneal angle, in this case with adhesion of the base of the iris to the peripheral cornea (peripheral anterior synechia). Note the retinal detachment and the abnormal shape of the lens (the latter resulting from loss of lens material at the time of perforation). Masson trichrome stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

20.2.2.1.3.2

### Secondary glaucoma

Anything capable of obstructing the flow of aqueous through the pupil or its exit through the trabecular meshwork can cause secondary glaucoma. The most common are listed next more or less in the order of frequency in dogs, the species in which glaucoma is by far the most prevalent. These mechanisms are not mutually exclusive, and frequently several different mechanisms act together to produce glaucoma. It is also undoubtedly true that dogs with goniodysgenesis are particularly prone to the development of secondary glaucoma, even when the degree of pupillary or trabecular occlusion is less than would be required to produce glaucoma in normal dogs.

1381

1382

**Fig. 20-41 Secondary glaucoma (from intumescent cataract), globe, sagittal section, dog.** Hydropic swelling of the lens (intumescent cataract) secondary to diabetes mellitus has caused the iris to be compressed against the peripheral cornea, resulting in a functional peripheral anterior synechia and a secondary glaucoma. The lens has subsequently ruptured, triggering a phacoclastic uveitis that explains the coagulated protein visible within the lens and ocular chambers. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

20.2.2.1.3.2.1

### Pupillary block.

The passage of aqueous through the pupil may be blocked by the anterior movement of the vitreous following primary anterior lens luxation by posterior synechiae as a sequela to fibrinous iridocorneal adhesions or by extension of a preiridal fibrovascular membrane (Fig. 20-40). Blockage may also occur from migration and fibroblastic metaplasia of lens epithelium that has been freed by rupture of the lens capsule or by massive swelling of the lens in what is known as intumescent cataract (Fig. 20-41). Displacement of the lens into the posterior chamber (posterior lens luxation) does not result in prolapse of the vitreous or in glaucoma.

20.2.2.1.3.2.2

### Trabecular occlusion.

The trabecular meshwork extends the full circumference around the iridocorneal angle, and no one is sure how much occlusion is required to produce glaucoma. The general consensus among ophthalmologists is that it must be at least 80%. The most common causes for this type of diffuse occlusion are infiltration by neoplastic cells (Fig. 20-42 and Box 20-10), peripheral iridocorneal adhesions by preiridal fibrovascular membranes (Fig. 20-43), or mechanical compression of the base of the iris by intumescent cataract or by large posterior chamber neoplasms. The tumors that most frequently cause glaucoma by infiltration of the trabecular meshwork are anterior uveal melanocytoma and metastatic lymphoma in dogs, and diffuse iris melanoma and metastatic lymphoma in cats. Glaucoma caused by compression of the base of the iris is less frequent because it requires a very large tumor to cause the nearly circumferential occlusion. Only anterior uveal melanocytomas in dogs are likely to fulfill this requirement.

1382

1383

**Fig. 20-42 Secondary glaucoma (from metastatic lymphoma), globe, sagittal section, dog.** The trabecular meshwork has been occluded by metastatic lymphoma within the anterior uvea and anterior chamber. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.2.2.1.3.2.2.1

### Box 20-10 How Intraocular Neoplasms Cause Glaucoma

Direct infiltration of the trabecular meshwork

- Feline diffuse iris melanoma
- Canine anterior uveal melanocytoma

Production of angiogenic growth factors that cause a preiridal fibrovascular membrane leading to pupillary block and/or trabecular occlusion

- Iridociliary adenoma/adenocarcinoma

Triggering of intraocular inflammation with posterior synechia and pupillary block or serous choroidal effusion with retinal detachment and preiridal fibrovascular membrane

- Metastatic carcinomas
- Malignant lymphoma

Primary intraocular neoplasms, with the exception of feline ocular sarcoma, have little metastatic risk and usually become medically significant by causing glaucoma.

**Fig. 20-43 Secondary glaucoma (from preiridal fibrovascular membrane), globe, sagittal section, dog.** The mature membrane has grown across the anterior surface of the pectinate ligament, creating peripheral anterior synechia. The trigger for the formation of the preiridal fibrovascular membrane was a small, otherwise insignificant iridociliary adenoma (not visible here). H&E stain. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Very occasionally glaucoma is caused by the occlusion of the trabecular meshwork by particulate material, such as erythrocytes or leukocytes. It might seem that such occlusion would be prevalent, but such material usually settles by gravity and temporarily occludes only the ventral portion of the filtration angle.

### 20.2.3 DISEASES OF THE CORNEA

#### 20.2.3.1 CORNEAL ANOMALIES

##### 20.2.3.1.1 Dermoid

Dermoid is the only corneal anomaly that is reasonably prevalent. It reflects the failure of the fetal ectoderm to undergo complete corneal “metaplasia,” with the result that a portion of the cornea remains as skin. Clinically, it is visible as a focus of corneal opacity in which there is hair, and histologically as a segment of cornea that is more or less identical to normal skin ([Fig. 20-44](#)). The degree of skinlike change varies from complete development of skin and hair follicles to a less extreme version in which only vestigial hair follicles are present.

#### 20.2.3.2 ACQUIRED CORNEAL DISEASES

##### 20.2.3.2.1 Superficial Stromal Sequestration/Canine Persistent Ulcer

In dogs, cats, and horses (and probably in other species), there is a syndrome in which injury to the corneal epithelium is followed by an increased amount of superficial stromal apoptosis above the small amount that normally follows any corneal epithelial injury. In dogs and horses, this results in an inability of the sliding corneal epithelium to properly adhere to the underlying stroma, which is a prerequisite for full epithelial regeneration. Initially, adhesion of the sliding epithelium is to fibronectin and other transient adhesion molecules, but permanent adhesion requires the reformation of basement membrane, hemidesmosomes, and hemidesmosomal anchoring filaments, which extend through the basement membrane to anchor into the superficial stroma. If that stroma is abnormal, these filaments cannot grip, and the regenerating epithelium is easily swept away with even the mildest trauma ([Fig. 20-45](#)). The cause for the excessive amount and/or persistence of the superficial stromal degeneration is not known. The most effective therapy is to surgically remove the superficial stroma (i.e., superficial keratectomy) to permit the epithelium to anchor into the normal deeper stroma.

Fig. 20-44 **Dermoid, cornea, dog.** A plaque of haired skin exists in place of the normal peripheral cornea. What triggers the failure of normal corneal maturation from pluripotential fetal ectoderm is unknown. Its clinical significance depends on how much corneal irritation is caused by the hair. Such dermoids may arise in cornea or, more commonly, bulbar conjunctiva. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

In cats, the magnitude of the stromal devitalization is much greater, and there is imbibition of brown-colored pigment (thought to be derived from porphyrins in the tear film) into the dead stroma. This results in a very characteristic central corneal dark brown pigmentation that is the predominant and essentially pathognomonic feature of this disease (Figs. 20-46 and 20-47). The overlying epithelium may be ulcerated as it is in dogs or horses, but in many cases it re-forms over the surface of the dead stroma. The frequency of this disease is much higher in those breeds with flat faces and prominent eyes, such as Persians and Himalayans, presumably because these eyes are predisposed to desiccation and other types of mechanical corneal injury. In non-Persian breeds with normal facial configuration, there is some evidence that ulceration caused by the herpesvirus is the most common predisposing cause.

1383

1384

Fig. 20-45 **Persistent ulcer, cornea, dog.** The epithelium is thickened and disorganized and has failed to adhere to the adjacent corneal stroma. This failure of adhesion results in ineffective wound healing, seen clinically as either persistent or repeated ulceration. The failure of epithelial adhesion probably occurs because the hemidesmosomal anchoring filaments are unable to “anchor” in the injured stroma. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Fig. 20-46 **Corneal sequestrum, cornea, cat.** The axial corneal ulcer has been accentuated by the absorption of a brown pigment, probably derived from porphyrins in the tear film. The gray halo of corneal edema and the prominent vascular ingrowth from the limbus to the edge of the ulcer are frequent but inconsistent features. (Courtesy Dr. M. Zigler, Mississauga-Oakville Veterinary Emergency Clinic.)

## Pathologic Basis of Veterinary Disease, 4th Edition

20.2.3.2.1.1

### Suppurative keratomalacia (“melting ulcer”)

Ulcers that become contaminated with bacteria or fungi are prone to suppurative destructive keratomalacia. Most of the stromal dissolution is probably the result of bystander injury from neutrophils recruited because of infection, but part of the damage may be associated with proteases of bacterial or fungal origin. *Pseudomonas* and streptococcus are the bacteria most likely to cause suppurative keratomalacia, which sometimes rapidly progress to descemetocoele and corneal perforation (Fig. 20-51). Contamination by opportunistic hyphal fungi (especially *Aspergillus* spp.) is a particularly frequent cause of keratomalacia in horses (see Equine Keratomycosis).

**Fig. 20-47 Corneal sequestrum, cornea, cat.** Note the complete loss of epithelium on the right two thirds of the cornea (ulcer) and the necrosis of the remaining epithelium (*left third*). The stroma under the ulcer is necrotic (deeper eosinophilic) to a depth of approximately half the thickness of the cornea. The necrotic epithelium, the thickened basement membrane, and some of the necrotic stroma are accentuated by brown porphyrin pigment from the tears. Corneal sequestra also occur in the dog and horse, but they do not become pigmented. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.2.3.2.2

### Infectious Bovine Keratoconjunctivitis

Infectious bovine keratoconjunctivitis (commonly known as “pink-eye”) is a worldwide contagious disease of considerable economic importance that has been recognized for more than 100 years. It is caused by specific strains of the gram-negative bacillus *Moraxella bovis*, which is part of the normal conjunctival and nasal flora of cattle. Virulent strains have capsular pili, which facilitate corneal colonization, and most of the virulent strains are also hemolytic. In contrast, most of the strains

## Pathologic Basis of Veterinary Disease, 4th Edition

recovered from the conjunctiva of healthy animals are nonhemolytic and nonpiliated. It is not clear exactly what is responsible for emergence of the virulent strains. *Moraxella bovis* is transmitted from animal to animal by mechanical vectors such as flies, by direct contact, and by fomites. In natural outbreaks, face flies (*Musca autumnalis*) appear to be the most important vectors. The concurrent presence of other infectious agents, such as *Mycoplasma* or infectious rhinotracheitis virus, often increases the severity of the disease.

1384

1385

**Fig. 20-48 Infectious bovine keratoconjunctivitis (“pink-eye”), cow.**

The axial half of the ulcerated cornea is filled with neutrophils (suppurative keratomalacia) and surrounded by a border of red fleshy granulation tissue. The initial lesions are shallow corneal ulcers and foci of suppurative superficial stromal keratitis with conjunctival hyperemia, followed by circumferential superficial vascular ingrowth from bulbar conjunctiva toward the central ulcers. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

The initial lesions are shallow corneal ulcers, which are probably the direct result of epithelial cytotoxin produced by adherent *Moraxella*. The organisms then gain access to the stroma, which results in attraction of large numbers of neutrophils from the limbus and from conjunctival blood vessels via the tear film. Inevitably, there is bystander injury from the degranulating neutrophils, but *Moraxella* also produces a potent cytotoxin, which accelerates neutrophil destruction. Lesions are initially unilateral but eventually become bilateral. Progression of a lesion is rapid during the initial 48 to 72 hours following infection, and usually results in a shallow painful corneal ulcer and foci of suppurative superficial stromal keratitis that gradually heal over the next few weeks. There is usually severe conjunctival hyperemia, followed by circumferential superficial vascular ingrowth from bulbar conjunctiva toward the central ulcers (Fig. 20-48). Healing involves the usual events of fibrovascular ingrowth from the

## Pathologic Basis of Veterinary Disease, 4th Edition

limbus, resulting in permanent central corneal scarring, which is usually not functionally significant. In severe cases, the ulcer may progress to descemetocoele, iris prolapse, and destruction of the globe.

Similar clinical and histologic entities exist in sheep, goats, and pigs associated with corneal colonization by *Chlamydia* spp. and *Mycoplasma* spp.

### 20.2.3.2.3

#### Feline Herpetic Keratitis

Feline herpesvirus 1 (FHV-1) is an exceedingly common cause of acute-to-chronic keratitis in cats. Viral infection of the corneal epithelial cells results in shallow intraepithelial branching tracts of necrosis, known as “dendritic” ulcers. FHV-1 can also cause a more severe delayed, deeper stromal accumulation of lymphocytes and plasma cells that appears to be a syndrome separate from the dendritic ulcers. In cats with deeper stromal keratitis, there is concurrent nondendritic regional epithelial ulceration, necrosis of superficial stroma, and an intense accumulation of lymphocytes and plasma cells that presumably have migrated from the limbus. The histologic pattern is nonspecific, and a more definitive etiologic diagnosis requires the demonstration of viral antigen within the injured epithelium or in the deep stromal lesion. Most cases of herpetic stromal keratitis probably result from activation of latent infections precipitated by concurrent disease or the topical application of corticosteroids. The specific etiologic diagnosis can be problematic because viral antigen can be difficult to demonstrate in chronic lesions laden with a lot of neutralizing antibody. In addition, many cats are asymptomatic carriers and so the mere demonstration of the FHV-1 (by immunohistochemistry or polymerase chain reaction [PCR] done on diseased corneas) is not sufficient to establish causation.

### 20.2.3.2.4

#### Eosinophilic Keratitis

Eosinophilic keratitis is a unique disease that occurs predominantly in cats but has been seen occasionally in horses. The macroscopic appearance is characteristic: a granular white proliferative lesion extending inwardly along what seems to be the corneal surface from the medial or lateral limbus. Many cases have similar lesions in the adjacent conjunctiva, and in a few cases the lesions are exclusively conjunctival. Most begin as a unilateral disease, but soon both eyes are involved. The histologic lesion is a nonulcerative superficial stromal infiltration of a mixture of eosinophils, plasma cells, mast cells, and macrophages. The percentage of each cell type within the lesion varies with the duration of the disease and is significantly influenced by therapy, but eosinophils are always present and are a requirement for the diagnosis. The granular appearance of the macroscopic lesion is created by the degranulation of eosinophils, which create a thick refractile eosinophilic coagulum along the surface of the lesion (Fig. 20-49). The diagnosis is usually made on the basis of clinical appearance and the presence of eosinophils in a superficial corneal scraping. Even a few eosinophils in a superficial stromal keratitis with compatible clinical signs should be diagnosed as chronic eosinophilic keratitis, even though the majority of the leukocytes are plasma cells or other mononuclear leukocytes.

The cause and pathogenesis are unknown. Affected cats do not have concurrent skin lesions of eosinophilic granuloma complex or any other concurrent disease. Between 70% and 80% of lesions contain the DNA of FHV-1; the problem is that ocular herpesviruses infection is so common in cats that a definitive causal link is difficult to establish.

1385

1386

**Fig. 20-49 Feline eosinophilic keratitis, cornea (keratectomy sample), cat.** The corneal epithelium and superficial stroma have been replaced by a coagulum of eosinophil granules. A mixture of leukocytes, predominantly eosinophils, has infiltrated the underlying stroma. The histologic changes are highly variable depending on the stage of the disease, but eosinophils are always present. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.2.3.2.5

### Canine Pannus Keratitis (Chronic Superficial Keratitis, Ueberreiter's Syndrome)

Pannus is a clinically and histologically distinctive superficial stromal keratitis seen primarily, but not exclusively, in German shepherd dogs. The disease usually begins at the lateral limbus as red conjunctival thickening. The lesion spreads toward the axial cornea as a superficial, fleshy, vascularized stromal infiltrate, involving both eyes (Fig. 20-50). Older lesions become intensely pigmented, and eventually the entire superficial stroma may be vascularized, scarred, and pigmented. The frequency and the severity of the disease increase proportionately as altitude increases, suggesting that sunlight exposure is important either in the initiation or the progression of the disease.

The histologic changes are almost identical to those seen in cutaneous discoid lupus, another disease with a predilection for German shepherds and related breeds. Discoid lupus is also exacerbated by sunlight. The early lesion is characterized by infiltration of plasma cells and smaller numbers of lymphocytes into the basilar half of the epithelium and the adjacent superficial corneal stroma near the limbus. There is vacuolation and then patchy loss of basal cells, followed by the dispersal of pigment from the injured epithelial cells. This is phagocytosed by macrophages, which accumulate within the superficial stroma. As the disease progresses, cellular infiltration is accompanied by corneal vascularization and fibrosis.

Fig. 20-50 **Pannus keratitis, cornea, German shepherd dog.** Note the fleshy gray-pink superficial stromal ingrowth from the lateral limbus (*right*) into the anterior stroma of the cornea. This appearance is classic for pannus. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

The disease is successfully treated (but never cured) by immunosuppressive therapy identical to that used to treat cutaneous discoid lupus. The inability to identify an infectious agent and the response to immunosuppressive therapy suggests that the disease has an immunologic pathogenesis, but the exact mechanism remains elusive.

### 20.2.3.2.6

#### Equine Keratomycosis

Equine keratomycosis (mycotic keratitis) is probably always a manifestation of opportunistic contamination of corneal wounds by fungi that are common within the environment around horses. *Aspergillus* spp. is by far the most common agent isolated. Similar infection occurs, much less frequently, in dogs, cats, and other species. Alteration of the corneal defenses or the normal microbial environment by the prolonged use of antibiotics or corticosteroids in the management of corneal wounds is a strong predisposing factor in all species. In all species there are two different syndromes: opportunistic infection of dead superficial stroma by huge numbers of fungal hyphae in the almost complete absence of inflammation, or deep stromal infection that evokes an intense suppurative keratomalacia that, if untreated, often progresses to corneal perforation and iris prolapse. The deep stromal keratitis in cases in which the stroma and epithelium have healed over the top of a deep stromal infection is referred to as a "stromal abscess." The fungi exhibit strong tropism for Descemet's membrane (as they do for basement membranes in other tissues), and may be absent from the stroma of

1386

1387

## Pathologic Basis of Veterinary Disease, 4th Edition

the superficial (anterior) half of the cornea (Fig. 20-51). This explains why confirmation of infection by means of corneal scrapings is often unsuccessful. It also explains why topical application of antifungal medication alone is rarely successful. In many cases, successful management of the disease requires surgical débridement of the cornea to remove most of the infected tissue and the damaging leukocytes. One peculiarity of this disease is that there is virtually never spread of the infection into the globe itself, even though the fungi can be seen dangling within the anterior chamber. There must be something unique to the corneal environment that is essential for fungal virulence or survival.

**Fig. 20-51 Suppurative keratomalacia (deep stromal), posterior cornea, keratomycosis, horse. A,** The deep portion of the corneal stroma contains numerous neutrophils, resulting in stromal destruction (keratomalacia). Descemet's membrane (*red*) is thickened and irregular and contains fungal hyphae. This is the most common histologic form of the disease. H&E stain. **B,** Higher magnification to show fungal hyphae within and adjacent to Descemet's membrane. Note the loss of the normal appearance of the stroma and the infiltration by neutrophils and edema fluid. H&E stain. (*A and B, Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

### 20.2.3.3 CORNEAL DYSTROPHIES AND DEPOSITIONS

Macroscopic examination of the cornea often reveals various types of colored or refractile stromal deposits. Some of these have already been discussed (superficial stromal pigmentation as part of cutaneous metaplasia or accumulation of leukocytes as part of stromal inflammation). Most other corneal deposits are composed of lipid and/or mineral. Among the domestic animals, they are most often seen in dogs. These deposits generally have characteristic clinical features (breed, age, exact anatomic location, and macroscopic appearance) that allow a diagnosis to be made without the need for histopathologic examination. They fall into two broad categories: inborn errors of metabolism known as corneal dystrophies, and acquired corneal deposits resulting from previous corneal disease or as incidental manifestations of systemic metabolic abnormalities that have “overflowed” into the cornea.

Genetically conditioned canine corneal stromal dystrophies include a seemingly endless array of lipid or mineral deposits somewhere within the corneal stroma. By definition, the defect is bilateral and congenital, even though the clinical or histologic manifestation of the abnormality may not be visible until later in life. The list of affected breeds grows daily. In each breed, the location, clinical character, and progression of the lesion is characteristic. In many, the exact nature of the deposit has not been characterized, but cholesterol, phospholipid, or lipid-calcium complexes, either alone or in combination, have been identified in some.

Corneal endothelial dystrophy is seen in several breeds of dogs as bilateral, diffuse corneal edema secondary to the progressive destruction of corneal endothelial cells. The edema is not accompanied by any evidence of inflammation or stromal fibrosis (Fig. 20-52) and usually begins at the lateral peripheral cornea and progresses over months-to-years to create diffuse edema. The microscopic lesion is extremely difficult to see because the corneal endothelial cells are generally not well preserved in histologic sections. Scanning electron microscopy and other specialized techniques demonstrate a progressive decrease in the number of corneal endothelial cells over time. The exact pathogenesis remains unknown.

Acquired corneal lipidosis (lipid keratopathy) results in milky or crystalline stromal deposits of serum lipids within the corneal stroma. The location depends on the pathogenesis. Any animal with an excessively high serum lipid concentration is predisposed to the deposition of neutral fat and cholesterol within the peripheral corneal stroma, reflecting an overflow from the limbal blood vessels. The lipid deposits become greatly accentuated if there is corneal inflammation because vascularization is increased and immature blood vessels are notoriously leaky.

1387

1388

**Fig. 20-52 Corneal endothelial dystrophy (inherited), cornea, Boston terrier, dog.** The gray appearance of the corneas is due to severe diffuse corneal edema. The edema is secondary to progressive loss of corneal endothelial cells. The pathogenesis of this loss is unknown, but because these cells are critical in regulating the movement of water and electrolytes from the aqueous humor into the corneal stroma, their loss results in passive absorption of water into the cornea from the aqueous humor. (Courtesy Dr. M. Nasisse, Carolina Veterinary Specialists.)

The microscopic changes associated with corneal lipid deposition include the presence of the lipid material and variable degrees of reaction to those deposits. Stromal keratocytes may accumulate small lipid vacuoles, and clefts of cholesterol will usually be found among the stromal fibers. In some cases there is virtually no inflammatory reaction, whereas in other dogs there is a well-developed granulomatous inflammatory reaction.

### 20.2.4 DISEASES OF THE UVEA

#### 20.2.4.1 UVEAL ANOMALIES

The epithelium on the posterior surface of the iris, the inner surface of the ciliary body, and the retinal pigment epithelium on the inner surface of the choroid are all derived from portions of the original optic vesicle. The bulk of the uvea is fibrovascular stroma derived from the periocular mesenchyme that originates from the neural crest ([Fig. 20-29](#)). Following outgrowth and later invagination of the primary optic vesicle to form the optic cup, the intraocular migration of this mesenchyme and its subsequent remodeling seem to be guided by soluble factors released from the neurectoderm; failures of proper induction, remodeling, and eventual atrophy of portions of this mesenchyme are among the most prevalent of ocular anomalies.

Table 20-1 Uveal Anomalies

Failure of Formation	Failure of Remodeling
Iris hypoplasia	Goniodysgenesis
Choroidal hypoplasia and sequelae	Persistent pupillary membrane
	Persistent hyaloid/primary vitreous
	Anterior segment dysgenesis
Lists are arranged from most prevalent to least prevalent.	

The anomalies of the uveal tract can be divided into those resulting from a failure of initial induction or migration, a failure of later remodeling, or a failure of eventual atrophy (Table 20-1). During early embryogenesis there is a persistent gap between the anterior lip of the optic cup and the overlying corneal epithelium. Through that gap will migrate several waves of periocular mesenchyme to form the corneal stroma and endothelium, the stroma of the anterior uvea, and the anterior portion of the perilenticular vascular tunic. The ingrowth of mesenchyme to form the iris stroma is guided by the infolding of the most anterior margin of the optic cup, which will form the two layers of the future iris epithelium. Later, papillary proliferation of that iris epithelium gives rise to the epithelium of the ciliary processes. Proper inward migration of the neurectoderm at the anterior lip of the optic cup seems to be a prerequisite for the subsequent migration of the mesenchyme to form the stroma of the iris and ciliary body (Fig. 20-53). Similarly, proper maturation of the future retinal pigment epithelium from the posterior neurectoderm of the optic cup is required for the proper maturation of the retina, choroid, and overlying sclera.

20.2.4.1.1

### Iris Hypoplasia

Failure of ingrowth of the future iris epithelium results in the relatively rare anomaly of extreme iris hypoplasia, clinically referred to as aniridia (Fig. 20-54). This is relatively more frequent in horses than in other species. At least in some cases (and probably in most), it is inherited.

20.2.4.1.2

### Choroidal Hypoplasia

Choroidal hypoplasia is a common anomaly in the eyes of dogs and cats and is often associated with inadequate pigmentation of the retinal pigment epithelium and choroid. There are many examples in which lack of pigmentation and thinning of the choroid seems to have no effect on vision or any other aspect of ocular health (the so-called subalbinotic fundus). There is often an association between choroidal hypopigmentation, choroidal hyperplasia, and color dilution within the hair coat. Some are accepted as “normal for the breed” by genetic screening registries, although perhaps unwisely.

1388

1389

**Fig. 20-53 Normal anterior uvea, 1-day-old puppy.** The iris is just beginning to be formed by ingrowth of neurectoderm and associated mesenchyme from the anterior lip of the optic cup. Formation of the ciliary processes and trabecular meshwork will follow. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

There are other instances in which choroidal hypoplasia is part of a significant developmental anomaly involving the choroids, retina, optic nerve, and sclera. By far the most important example is collie eye anomaly. There are very similar anomalies in phenotypically related breeds, such as the Shetland sheepdog and Australian shepherd dog.

Collie eye anomaly was first described in 1953 as a widespread disease in smooth and rough collies in North America, Europe, and England. During the 1970s, it was found in more than 70% of collies within United States, often with devastating consequences for vision. The multitude of anomalies can all be explained by a single fundamental defect in the proper induction of the retinal pigment epithelium. The most basic and most prevalent of those inductive failures is hypoplasia and hypopigmentation of the choroid, which is why the disease is included here.

The fundamental defect in this anomaly appears to be improper inductive chemical signaling from the developing RPE. Choroidal development (in dogs and many other species) is in some way linked to the acquisition of melanin pigmentation. As a result of this defective signaling, the periocular mesenchyme destined to form the choroid and the sclera receives insufficient stimulation. In the choroid, this outcome

## Pathologic Basis of Veterinary Disease, 4th Edition

is manifest as hypopigmentation and hypoplasia, including hypoplasia of the tapetum (Fig. 20-55). Within the fibrous tunic of the sclera, the most common manifestation is arrested growth, which results in delayed closure of the optic fissure along the ventral floor of the optic cup. That delay in closure allows the growing retina to bulge outwardly through the most posterior portion of this optic fissure. This outward protrusion of retina, usually just ventral to the optic disc, permanently prevents the proper closure of the embryonic fissure and sclera. The combined defect is referred to as posterior polar (or optic disc) coloboma, which produces a bulging of the sclera known as scleral ectasia (Fig. 20-56).

**Fig. 20-54 Iris hypoplasia, piglet.** There is no ingrowth of iris epithelium, and the periocular mesenchyme has therefore not migrated inward to form the iris stroma. Unexpectedly, the ciliary processes have formed normally but have arrested maturation in that they have not retracted from the lens capsule. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Other common defects in collie eye anomaly include mild microphthalmia, congenital retinal folding, tapetal hypoplasia, and retinal detachment. Detachment is usually delayed until the puppy is a few months of age and is not present at birth. Both the microphthalmia (which is usually just mild) and the retinal folding (see later under Retinal Dysplasia) probably represent improper coordination of the rates of retinal and scleral growth and are probably another manifestation of improper signaling from the RPE. A retinal growth rate that exceeds that of the scleral shell will inevitably result in folding of the redundant retina (interestingly, these retinal folds will usually disappear as retinal and scleral growth eventually normalize). Conversely, normal growth of the scleral shell, accompanied by deficient retinal growth, will stretch the retina and eventually result in complete retinal detachment (Fig. 20-57).

1389

1390

Fig. 20-55 **Choroidal hypoplasia, collie eye anomaly, choroid, dog.** **A**, The choroid is only about half normal thickness and has no pigment. These lesions are the most consistent of those described for collie eye anomaly, but the molecular basis remains unknown. H&E stain. **B**, Normal canine retina and choroid, age-matched control. **C**, Choroid; **S**, sclera. H&E stain. (**A** and **B**, Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

20.2.4.1.3

### Other Uveal Abnormalities

Goniodysgenesis is maldevelopment of the filtration angle and is exceedingly common as a cause of primary glaucoma in dogs, but it is much less frequent in other species. It results from incomplete atrophy of the mesenchyme at the base of the iris. Most of this remodeling occurs in the first few weeks of life. For reasons that are poorly understood, clinical manifestations of glaucoma attributed to this developmental anomaly are not usually detected until middle-age or even later. Goniodysgenesis is described in more detail in the section under Glaucoma.

1390

1391

**Fig. 20-56 Posterior polar scleral ectasia (at a site of coloboma), collie eye anomaly, eye, posterior pole, sagittal section, dog.** The retina protrudes through a defect in the posterior pole of the globe, a sequel to the delayed closure of the posterior margin of the embryonic fissure. The protruding retina is covered by sclera that also bulges posteriorly to accommodate the retinal protrusion. The lack of synchronization between the retinal and scleral growth rate that is part of collie eye anomaly causes retinal folding and, later, retinal detachment. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Fig. 20-57 **Retinal detachment (complete), collie eye anomaly, globe, sagittal section, dog.** The retina remains attached only at the sites of its true anatomic attachment: the optic disc and its junction with the pars plana of the ciliary body. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

AC, Anterior chamber; LE, lens epithelium. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

*Persistent pupillary membranes* and *persistent primary vitreous* refer to abnormal persistence of portions of the perilenticular vascular tunic or the vascular network within the developing vitreous. Such anomalies are common in dogs. The embryonic lens is encased in a network of blood vessels known as the tunica vasculosa lentis (Fig. 20-58). That network is created by contributions from the same mesenchyme that forms the iris stroma and from vasogenic mesenchyme growing into the developing vitreous through the posterior portion of the slowly closing optic fissure. The latter vessels, growing in from near the optic disc, are the hyaloid artery system (Fig. 20-29). Together with other nonangiogenic mesenchymal elements, these vessels form the primary vitreous. This embryonic hyaloid artery system creates a temporary vascular network along the surface of the developing retina and also joins with the anterior chamber vessels to complete the tunica vasculosa lentis. All portions of this elaborate vascular system undergo atrophy before maturation of the globe. Persistence of one or more portions is common. The most common is persistence of the anterior portion of the tunica vasculosa lentis. This is usually referred to as persistent pupillary membrane. Macroscopically, these are seen as fine threads originating from the minor arterial circle of the iris. They are usually bloodless but are often pigmented. They may be inserted into the anterior stroma of the iris, or they may contact the surface of the lens (Fig. 20-59). Occasionally, in what is probably a more significant anomaly, they insert into the cornea. These membranes become clinically significant if they contact the lens or cornea, where they interfere with proper development of corneal or lens epithelium, or their associated basement membranes (Descemet's membrane and lens capsule, respectively). Histologically, persistent pupillary membranes are thin endothelial tubes accompanied by varying amounts of mesenchymal stroma. At sites of corneal contact, they may cause fibrous metaplasia of the corneal endothelium. Where they contact the lens, there will usually be epithelial proliferation and dysplasia of the lens capsule, resulting in a permanent focal cataract (Fig. 20-60). Those cases in which the pupillary membranes contact the cornea are probably more correctly classified as a minor expression of anterior segment dysgenesis (see later discussion).

**Fig. 20-59 Persistent pupillary membrane, 6-month-old dog.** These persisting portions of the tunica vasculosa lentis have adhered to the anterior surface of the lens, causing anterior polar lens opacity. (Courtesy pathology archives, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Persistence of various portions of the hyaloid artery system, with or without other portions of the primary vitreous, include much less common anomalies known as persistent hyaloid artery, and persistent (hyperplastic) primary vitreous (Fig. 20-61). When persistent blood vessels are accompanied by hyperplastic nonangiogenic mesenchymal spindle cells, the resulting anomaly is known as persistent hyperplastic primary vitreous. It has been described as a prevalent familial lesion in several breeds of dogs, particularly Doberman pinschers. The nonangiogenic mesenchyme undergoes notable fibroblastic proliferation, sometimes with cartilaginous metaplasia. Most affected dogs have concurrent anomalies, such as persistent pupillary membrane, microphthalmia, congenital cataract, and abnormal lenticular shape. Many of the described cases do not have the full range of lesions required for the diagnosis of persistent hyperplastic primary vitreous. Most would be better classified as persistent posterior tunica vasculosa lentis because the “hyperplastic” lesions of vitreal mesenchymal proliferation are absent.

1391

1392

**Fig. 20-60 Persistent pupillary membrane, dog.** These membranes (arrows) have adhered to the anterior lens capsule, resulting in disorganized proliferation of lens epithelium and lens capsule. The result is an anterior polar cataract. Periodic acid–Schiff reaction. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

**Fig. 20-61 Persistent hyaloid artery and posterior portions of the tunica vasculosa lentis, globe, sagittal section, dog.** A stalk of fibrovascular tissue (the fetal hyaloid artery and associated mesenchyme) extends from the optic disc to ramify over the posterior surface of the lens. Opacity and deformity of the posterior pole of the lens are frequent complications. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

Anterior segment dysgenesis is a blanket term for a variety of rare anomalies in which there is a failure of remodeling of the periocular mesenchyme destined to create the corneal stroma, corneal endothelium, iris stroma, and the anterior portion of the tunica vasculosa lentis. The usual clinical observation is absence of anterior chamber and the apparent fusion of the iris stroma to the corneal stroma, and no corneal endothelium or Descemet's membrane. The vast majority of these cases are not primary developmental anomalies but the result of perinatal corneal perforation. The loss of the anterior chamber is thus the result of a diffuse anterior synechia, usually secondary to traumatic corneal perforation or perforating ulcers that result in subsequent iris prolapse.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

20.2.4.1.4

### Acquired Uveal Diseases

There are in excess of 50 different etiologic types of uveitis in dogs alone, but in most of these the uveitis is only an incidental part of a systemic disease. The macroscopic or microscopic lesions within the globe are usually not distinctive, and diagnosis of the disease is rarely made on the basis of ocular lesions. Even when uveitis is the only clinical sign of disease, rarely is an etiologic diagnosis made. Many of the specific examples of uveitis listed in clinical textbooks are syndromes made distinctive by clinical features or by identification of a causal agent, rather than by distinctive histologic lesions. Listed next and in [Table 20-2](#) are the most common and most important examples of uveitis that do have distinctive histologic features.

20.2.4.1.5

### Idiopathic Lymphonodular Uveitis

Although not really a specific disease, this is by far the most common histologic pattern seen in uveitis. This may reflect in part a genuinely high frequency of immune-mediated uveitis. More likely, however, it is simply an indication of the chronicity of the uveitis because microscopic evaluation of globes with uveitis is usually done only in the chronic stages of disease, after all attempts at therapy have failed. Lymphonodular uveitis may therefore imply nothing more than a stereotypic endstage of uveitis that initially had a more distinctive and more variable histologic appearance. Lymphonodular uveitis was made famous by recurrent uveitis in horses. It is the only example of lymphonodular uveitis for which we have some insight into the actual cause, and for that reason it serves as the archetype for this group.

1392

Equine recurrent uveitis (periodic ophthalmia, moon blindness) (ERU) is a frequent cause of blindness in horses. It is characterized by unpredictable episodes of severe uveitis with a tendency to become increasingly frequent and increasingly severe over time. It is likely that several different diseases are included under this diagnostic umbrella, but at least one of the causes is an immunologic reaction against intraocular leptospiral antigens. It is thought to be a delayed reaction to a systemic infection with *Leptospira interrogans* (most often serovar *pomona*). The evidence supporting a role for leptospirosis in the pathogenesis of equine recurrent uveitis is substantial even if not absolutely conclusive:

1393

1. Horses with high serum titers to *Leptospira interrogans* are 13 times more likely to have uveitis than horses with no such titers.
2. Antileptospiral antibodies rise during episodes of uveitis and decrease during quiescent phases.
3. The disease can be reproduced by infection of naive horses with *Leptospira interrogans* serovar *pomona*. Not all infected horses developed uveitis, and the onset of ocular signs is usually delayed for a year or more after infection. In the original study, 22 of 36 of the eyes of Shetland ponies inoculated subcutaneously with small numbers of *Leptospira interrogans* serovar *pomona* eventually developed classic recurrent uveitis. All ponies developed leptospiremia soon after inoculation, but none developed ocular disease until at least 50 weeks later.
4. There is cross reaction between leptospiral antigens and various intraocular antigens, particularly those of the corneal endothelium and lens. This creates the possibility that the ongoing immune-mediated inflammation is not necessarily in response to persisting leptospiral antigens. Leptospirosis may cause the initial uveitis, but may not be responsible for its perpetuation.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 20-2 Frequent Causes of Uveitis

Dog	Cat	Horse
Idiopathic causes	Idiopathic causes	Recurrent uveitis
Phacolytic uveitis	Cryptococcosis	
Trauma	Feline infectious peritonitis	
Foreign body		
Blastomycosis		
Phacoclastic uveitis		
Lists are arranged from most prevalent to least prevalent.		

The most common alternative agent implicated in a syndrome clinically indistinguishable from leptospira-associated recurrent uveitis is *Onchocerca cervicalis*. Intraocular dead or dying microfilaria have been proposed as sources of antigen responsible for the disease.

**Fig. 20-62 Equine recurrent uveitis, iris, horse.** Perivascular lymphocytic-plasmacytic aggregates within the iris stroma are typical of equine recurrent uveitis, but the same lesion is commonly seen in idiopathic uveitis in various species. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The microscopic lesions depend on the stage of the disease and represent a continuum from anterior uveitis to endophthalmitis with retinal scarring, or even phthisis bulbi. The earliest lesion is an anterior uveal inflammation that is transiently neutrophilic but rapidly becomes predominantly lymphocytic. Even during intervals in which the clinical disease is quiescent, the histologic lesions of perivascular lymphocytic anterior uveitis persist (Fig. 20-62). Peripheral corneal vascularization becomes increasingly prominent, eventually extending across the entire diameter of the corneal stroma. Choroidal inflammation is usually most obvious near the optic disc and may cause exudative retinal detachment. Even if the retina reattaches, there will be residual lesions of photoreceptor loss, or even full thickness

## Pathologic Basis of Veterinary Disease, 4th Edition

retinal scarring as a result of ischemic injury during periods of detachment. This peripapillary retinal scarring is sometimes the only lesion seen in horses with a clinical history suggesting chronic, episodic ERU.

A characteristic lesion of chronic ERU is an eosinophilic hyaline membrane that seems to cover the ciliary epithelium. This material, in fact, lies within the apical cytoplasm of the nonpigmented ciliary epithelium and resembles amyloid. Its pathogenesis is unknown, but it serves as a useful marker for the disease.

Feline idiopathic lymphonodular uveitis is by far the most frequent histologic pattern of the uveitis in cats. It is important as a cause of the clinical signs of uveitis itself, but it is even more important as a very common cause of glaucoma in cats. The mechanism by which the uveitis causes the glaucoma is unknown; it is not by the usual mechanisms of posterior synechia or preiridal membrane formation. At the initial clinical presentation, the lesion may be unilateral, but in most cases the uveitis eventually becomes bilateral.

1393

1394

**Fig. 20-63 Idiopathic lymphonodular uveitis, anterior uvea, cat.** The iris and ciliary body contain numerous coalescing perivascular lymphocytic-plasmacytic nodules (*arrows*). This lesion is the most common cause of glaucoma in cats (vying with diffuse iris melanoma for that distinction), but the mechanism by which it causes glaucoma is unknown. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The microscopic lesions are essentially identical to those seen in equine recurrent uveitis: perivascular accumulations of lymphocytes and plasma cells throughout the anterior uvea, and with less regularity, within the choroid and around small vessels in the retina. The iris tends to have the greatest accumulation, and here the lymphocytic-plasmacytic perivascular aggregates may become so large as to be clinically visible (Fig. 20-63). The degree of iris thickening and pallor may be sufficient to make this lesion macroscopically indistinguishable from that of lymphoma (lymphosarcoma).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The cause remains a complete mystery despite considerable investigation. The syndrome is presumed to be immune mediated, but the identity of the antigen or antigens is unknown. Affected cats are no more likely to be seropositive or PCR-positive for the various feline systemic infectious agents (FIV, FIP, leukemia virus, etc.) than are healthy cats, but no credible cause has been demonstrated by immunohistochemical or PCR investigation of affected globes. Some believe strongly that a previous infection with *Toxoplasma* is somehow involved, but the evidence remains inconclusive.

Canine lymphocytic uveitis has the most frequent histologic pattern of uveitis seen in dogs (as it is in cats and horses), a lymphocytic-plasmacytic panuveitis that tends to be more severe in the anterior uvea than in the choroid. It should not really be considered a specific disease but rather a histologic pattern that is probably shared by many different diseases. As in the other species, the disease may be unilateral or bilateral and tends to occur in multiple episodes interrupted by periods of quiescence. The cause remains unknown, and it is likely that there are multiple different agents capable of inducing this identical histologic change. In contrast to the situation in cats, it does not cause glaucoma. The main differential diagnosis is phacolytic uveitis, and indeed in some cases the histologic distinction is impossible.

20.2.4.1.6

### Uveodermatologic Syndrome in Dogs (Vogt-Koyanagi-Harada Syndrome)

Despite the exotic-sounding name, this disease is relatively frequent in the most susceptible breeds (Akitas, Siberian huskies, Samoyeds). The clinical syndrome of facial dermal depigmentation and severe bilateral uveitis is distinctive, although many dogs with the uveitis do not have skin lesions. The canine syndrome closely parallels that of the human disease, except that the encephalitis, which is the least frequent part of the human syndrome, has not been confirmed in dogs. The histologic lesion is a destructive granulomatous endophthalmitis with abundant dispersal of melanin, a consequence of T-lymphocyte-mediated destruction of melanin-producing cells of the RPE and uvea. The disease is slowly progressive and is always eventually bilateral even though initially it may not affect both eyes.

20.2.4.1.7

### Systemic Mycoses

Systemic mycoses such as blastomycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis are frequent causes of severe uveitis in those geographic areas where the organisms are common environmental contaminants. Immunodeficient animals may develop endophthalmitis as part of generalized disease caused by saprophytic fungi such as *Aspergillus* spp. or *Candida* spp., but these cases are rare; these same agents will occasionally cause endophthalmitis when introduced by penetrating plant foreign bodies.

The frequency with which endophthalmitis accompanies systemic mycosis is unknown. The majority of cases are found in dogs, except for the inexplicable predilection of cryptococcosis for cats. Ocular involvement is part of systemic disease, but fairly frequently ocular disease is the only obvious clinical sign. Blastomycosis is by far the most prevalent example of an endophthalmitis caused by systemic mycosis, and it will serve here as the prototype for this group.

Blastomycosis is the most frequently reported intraocular mycosis in dogs, but it is rare in cats. It is estimated that about 25% of dogs with the systemic disease have clinically obvious ocular disease: unilateral or bilateral endophthalmitis with a very high frequency of exudative retinal detachment. The microscopic lesion is severe diffuse pyogranulomatous endophthalmitis, which tends to be more severe

1394

1395

## Pathologic Basis of Veterinary Disease, 4th Edition

---

in the choroid and subretinal space than in the anterior uvea. The greatest accumulation of both leukocytes and organisms is usually in the subretinal space. The disease is pyogranulomatous and very destructive. The organisms may be numerous or extremely sparse, probably depending on the duration of the disease and on therapy. They are either free or within the cytoplasm of macrophages and have the typical features of *Blastomyces* spp.: thick-walled yeast 4 to 20  $\mu\text{m}$  in diameter, with occasional broad-based budding. The diagnosis can often be made by cytologic evaluation of subretinal exudates in eyes that are already blind because of retinal detachment (one would probably not dare to attempt aspiration of the subretinal space in a globe that still had vision). Other lesions in affected globes are those seen in any severe uveitis: intraocular hemorrhage, posterior synechia, preiridal fibrovascular membrane, and cataract. Spread into the optic nerve and even orbit is an infrequent complication.

Cryptococcosis is similar to blastomycosis in that the lesions are predominantly within the retina, choroid, and optic nerve. As mentioned earlier, ocular cryptococcosis is immeasurably more prevalent in cats than in dogs or any other domestic animal. As is typical of cryptococcosis in other feline tissue, the granulomatous inflammatory response is often minimal. Large collections of poorly stained pleomorphic yeasts, surrounded by wide capsular halos, impart a typical “soap-bubble” appearance in hematoxylin and eosin (H&E) stained sections. The organisms are usually numerous and vary greatly in size and shape. In a few cases, the granulomatous reaction is much more severe and mimics that seen in blastomycosis. In such lesions, organisms are typically scarce.

The ocular disease caused by *Coccidioides immitis* resembles blastomycosis but is more suppurative, more destructive, and more prone to progress to outright panophthalmitis. Involvement of the anterior uvea is perhaps more common than in the other systemic mycoses. The disease is seen only in animals that live in (or have visited) the very restricted geographic regions in which the organism is common. The great majority of cases are seen in dogs from the desert regions of the American Southwest ([Fig. 20-64](#)).

The lesions caused by ocular infection with *Histoplasma capsulatum* are distinctive and quite different from those of the other systemic mycoses. There is usually a diffuse granulomatous and lymphocytic choroiditis with little suppuration and without much of the destruction that characterizes blastomycosis and coccidioidomycosis. Organisms are usually very numerous and visible as small spherical bodies within the cytoplasm of macrophages.

Fig. 20-64 **Granulomatous choroiditis (destructive), coccidioidomycosis, choroid, dog.** The retina is absent because inflammatory exudate has caused retinal detachment. Organisms are usually difficult to find, but two spherules (arrows) are amid the macrophages. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Protothecosis is included here because the organisms can easily be mistaken for yeast and because the clinical and histologic features closely resemble those of the systemic mycoses described earlier. Prototheca are colorless saprophytic algae capable of causing enteric, cutaneous, or generalized granulomatous disease in a variety of mammalian species. Ocular lesions have been described only in dogs with the disseminated form of the disease. The lesions are essentially identical to those seen with blastomycosis and are distinguishable only by the detection of the pleomorphic algae (which usually are very numerous). In histologic section, the algae are free or within macrophages. The organisms are spherical to oval, from 2 to 20  $\mu\text{m}$  in diameter, and have a refractile cell wall that stains with periodic acid–Schiff (PAS) reaction or Gomori's methenamine silver stain. Prototheca reproduces by asexual multiple fission, so that multiple daughter cells form enclosed within a single cell wall. There is no budding as with blastomyces and cryptococcus.

20.2.4.1.8

### Feline Infectious Peritonitis–Associated Uveitis

The coronavirus of feline infectious peritonitis causes a diffuse uveitis that is probably immune-mediated. The frequency of ocular lesions is unknown because the eyes are not regularly examined in cats with the disease. The histologic lesions in the globe are always bilateral and are similar to those seen in any other organ affected with the disease. As elsewhere, the lesions vary in the relative proportions of the different leukocyte types, the amount of fibrin, and the amount of necrosis. In most cases the disease is primarily an anterior uveitis with a mixture of lymphocytes, plasma cells,

1395

1396

## Pathologic Basis of Veterinary Disease, 4th Edition

neutrophils, and macrophages. Especially within the globe, the often-repeated statement that FIP causes “pyogranulomatous” inflammation is greatly exaggerated. The exudate within the anterior chamber is usually predominantly neutrophilic, yet in the choroid the inflammation is usually lymphocytic-plasmacytic. Formation of keratic precipitates and a neutrophilic corneal endothelialitis are strong indicators of an FIP-associated uveitis (Fig. 20-65). In many cases, there are also typical histologic lesions in the orbital soft tissue adjacent to the sclera and in the meninges of the optic nerve. There is no other cause of uveitis in cats that is also routinely involved in orbital cellulitis. Classic necrotizing vasculitis is seen only rarely, and if present, it is likely to be in the retina. Sequelae such as pupillary block and secondary glaucoma are rarely seen, simply because cats with ocular lesions of FIP are usually in the advanced stages of the systemic disease and do not survive long enough for those potential sequelae to develop.

**Fig. 20-65 Lymphocytic, granulomatous, and neutrophilic iridocyclitis (destructive), feline infectious peritonitis, ciliary body, cat.** Lymphocytes and plasma cells tend to predominate within the uveal stroma (*left*), whereas neutrophils, fibrin, and macrophages predominate within the adjacent aqueous humor of the posterior chamber (*right*). These lesions are typical of feline infectious peritonitis. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.2.4.1.9

### Bovine Malignant Catarrhal Fever–Associated Uveitis

The majority of cattle with malignant catarrhal fever have prominent ocular lesions in the form of peripheral midstromal corneal vascularization and obvious anterior uveitis. These lesions help to clinically distinguish this disease from mucosal disease and acute severe bovine viral diarrhea (BVD). The histologic lesions within the eye resemble those elsewhere in the body: arterial necrosis with

## Pathologic Basis of Veterinary Disease, 4th Edition

---

perivascular and intramural accumulation of lymphoblasts, among which are a few with mitotic figures. The vasculitis is most often identified within the iris, but it can be found anywhere within the uveal tract or retina. The accompanying uveitis is predominantly lymphocytic right from the start. Of great diagnostic significance from a clinical perspective is a ring of peripheral corneal stromal vascularization extending into the cornea from the limbus. The vascular ingrowth is accompanied by notable corneal edema. Although this is a routine lesion seen in any chronic severe uveitis, it is not seen in keratoconjunctivitis associated with several other bovine infectious diseases. There may be a concurrent lymphocytic corneal endothelialitis contributing to the corneal edema.

The pathogenesis of the disease remains controversial. The appearance of the vasculitis suggests that it should be an immune-mediated vasculitis, yet intramural deposition of immunoglobulin or complement is not a significant feature of the vascular lesion. A T-lymphocyte dependent, type IV immune pathogenesis has been suggested.

20.2.4.1.10

### Lens-Induced Uveitis

Phacolytic uveitis is an extremely common, mild lymphocytic-plasmacytic anterior uveitis that occurs in a large proportion of animals with cataracts in which the lens protein is beginning to disintegrate and leak through the intact lens capsule. Although seldom significant as the cause of clinical signs, it significantly reduces the success of cataract surgery, unless the surgery is preceded by a course of antiinflammatory drugs.

Phacoclastic uveitis is predominantly an immune-mediated disease in response to the release of large amounts of intact lens protein through a traumatically ruptured lens capsule. The severity and character of the reaction seem to be influenced by the amount of lens material lost, the speed of the loss, the age of the animal, and the species. The disease is most commonly seen in dogs because of their habit of running into sharp objects or having unpleasant encounters with the neighborhood cat. Lens rupture may also occur following blunt trauma, in which case the rupture is usually of the thin posterior capsule. Phacoclastic uveitis will also occur following spontaneous lens rupture, not associated with trauma. This occurs in rabbits as a result of penetration of the lens by *Encephalitozoon cuniculi* and in dogs with rapidly progressing diabetic cataracts.

The clinical syndrome is quite distinctive: The initial clinical signs are related to corneal perforation and uveitis as direct consequences of the penetrating injury and/or subsequent sepsis. Those are often managed successfully with antiinflammatory and antibiotic therapy, and everything seems to be healing very well until the development of a severe and therapeutically refractory anterior uveitis that most commonly occurs about 2 weeks after the initial injury. Once the phacoclastic uveitis is initiated, the prognosis for saving the globe becomes poor.

1396

1397

The lesions of phacoclastic uveitis are of two different types, usually occurring concurrently. The typical lesions in acute disease include rupture of the lens capsule, accumulation of intralenticular neutrophils, and a perilenticular inflammatory reaction that is initially neutrophilic. With time it becomes progressively more granulomatous but remains distinctly perilenticular (Fig. 20-66). After a few days, the inflammatory reaction is accompanied by proliferation, fibroblastic metaplasia, and perilenticular migration of lens epithelial cells that have escaped through the site of perforation (Fig. 20-67). Because the perforating injuries causing phacoclastic uveitis may also implant bacteria or foreign material into the globe, it is not always possible to determine what part of the posttraumatic lesion is phacoclastic uveitis and what part is in response to a foreign body or infection. True phacoclastic uveitis is distinctly perilenticular, with minimal reaction in more distant portions of the uvea, such as the choroid.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The pathogenesis of the inflammatory component of phacoclastic uveitis is probably an immunologic response to the release of large amounts of strongly antigenic lens protein into the aqueous humor. Although lens protein is not truly “foreign,” the body has tolerance for only small amounts of lens protein. The sudden release of large amounts following capsular rupture overwhelms this immune tolerance, resulting in a suppurative-to-pyogranulomatous reaction centered on the lens. This immune pathogenesis explains the lag between lens rupture and development of the phacoclastic uveitis. It also explains why small perforations might not cause the disease and why removal of the injured lens shortly after perforating injury prevents the development of the disease.

**Fig. 20-66 Phacoclastic uveitis, encephalitozoonosis, eye, sagittal section, rabbit.** The anterior lens capsule has disintegrated, with substantial loss of lens material from the anterior cortex. The scalloped remnant of lens is now covered by a mixture of fibrin and leukocytes that fills the anterior chamber. In all species, the sudden release of intact lens protein triggers massive suppurative and granulomatous perilenticular inflammation that is typically delayed until 10 to 14 days after lens rupture. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The fibrous metaplasia and migration of lens epithelium are critical prognostic events. This epithelium, once out of the lens, recognizes no barriers to its proliferation and will cause pupillary block, occlusion of the filtration angle, and secondary glaucoma. In cats, probably it is this same epithelium that undergoes malignant transformation to the clinically significant and uniquely feline entity of posttraumatic primary ocular sarcoma (see discussion on neoplasia).

## Pathologic Basis of Veterinary Disease, 4th Edition

Phacoclastic uveitis can be a serious complication of cataract surgery in which too much lens material is left behind within the lens capsular bag. In most instances, complications arise primarily from the migration and fibroblastic metaplasia of this residual lens epithelium. This can result in opacification of the pupil (and of any artificial lens implant) and possibly pupillary block, causing secondary glaucoma.

20.2.4.2

### NEOPLASMS OF THE UVEA

Primary uveal neoplasms are common only in dogs and cats, but they are exceedingly important in both species and vie with glaucoma as the most common reason for enucleation (Table 20-3). Primary tumors (melanocytic tumors and iridociliary epithelial tumors) are considerably more prevalent than metastatic tumors in the globe, with the possible exception of metastatic uveal lymphoma in cats.

1397

1398

**Fig. 20-67 Chronic phacoclastic uveitis, eye, horse.** The predominant lesion is now a plaque of fibroblast-like cells on the anterior surface of the lens adjacent to the site of capsular rupture (*lower left*). This plaque is created by metaplasia of lens epithelium that has escaped through the capsular defect. These proliferating cells frequently cause pupillary blockage and secondary glaucoma. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Table 20-3 Common Primary Intraocular Neoplasms

Dog	Cat	Horse
Anterior uveal melanocytoma	Diffuse iris melanoma	Medulloepithelioma
Iridociliary adenoma	Iridociliary adenoma	
	Primary ocular sarcoma	
Lists are arranged from most prevalent to least prevalent.		

**Fig. 20-68 Anterior uveal melanocytoma, eye, sagittal section, dog.** A large black tumor has replaced the anterior half of the uvea and filled much of the anterior chamber. (*Courtesy Dr. B. Wilcock, Ontario Veterinary College.*)

In all species, melanocytic tumors are by far the most common of all ocular tumors. Those tumors predicted to be behaviorally benign are referred to as melanocytomas; those predicted to be malignant are classified as melanomas. As with melanocytomas and melanomas elsewhere, there is substantial variation in biologic behavior depending on species and location. These site and species variables are more important in establishing the prognosis than are many of the histologic and cytologic features.

Canine anterior uveal melanocytoma is by far the most common primary intraocular tumor of dogs, arising from the melanocytes within the stroma of the iris or ciliary body. They ordinarily form a solid, deeply pigmented mass that protrudes into the anterior or posterior chamber. Growth is expansive rather than invasive (Fig. 20-68). The typical tumor has an inconspicuous germinal population of cytologically bland and poorly pigmented spindle cells, and a much larger proportion of huge ballooned “plump cells” distended with pigment (Fig. 20-69), which are assumed to be postmitotic endstage neoplastic melanocytes. These tumors have very little metastatic potential, and the few that are likely to metastasize can be identified by a notable increase in the numbers of mitotic figures. All of these tumors, sooner or later, grow large enough to cause obstruction of aqueous outflow and secondary glaucoma.

**Fig. 20-69 Anterior uveal melanocytoma, iris, dog.** Large, heavily pigmented polygonal “plump cells” predominate. The smaller number of lightly pigmented spindle cells are germinal cells. The paucity of mitotic figures is a predictor that the tumor is benign. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Histologically identical melanocytoma will very occasionally arise within the choroid as a slowly expanding subretinal mass. They are significant because they cause retinal detachment.

Feline diffuse iris melanoma has a distinctive clinical presentation: unilateral coalescing hyperpigmentation of the iris that slowly (often over many years) progresses to diffuse iris thickening and secondary glaucoma (Fig. 20-70). This is a uniquely feline disease. The tumor originates from the layer of melanocytes that forms the anterior border layer of the normal iris. The transformed cells have enlarged nuclei and hyperchromasia and proliferate slowly to replace the normal iris architecture. The fully developed tumor, as the name implies, results in a diffuse iridal infiltration by pleomorphic round-to-epithelioid melanocytes. Their appearance in cytologic preparations is extremely variable. Tumors vary from amelanotic to heavily pigmented, and from round cell to epithelioid to spindle cell (and mixtures of all of the above), but none of these variables has any prognostic significance. Mononuclear gigantism is frequently seen (Fig. 20-71). None of these variables has any prognostic significance.

1398

1399

The prognosis has been the subject of great debate over the past 10 years. Retrospective studies that have attempted to establish histologic predictors of behavior have been thwarted by poor overall follow-up data (cats lost to follow-up, very few necropsies). Nonetheless, emerging from these studies is the general consensus that although these tumors are substantially more likely to eventually metastasize than are canine uveal melanomas, the overall risk of an affected cat developing clinical signs related to metastatic disease seems to be low. The probability that the affected eye will eventually develop glaucoma secondary to tumor infiltration of the trabecular meshwork is exceedingly high, although it may take years.

Fig. 20-70 **Diffuse iris melanoma, eye, cat.** Coalescing areas of brown pigmentation have caused thickening of the iris. In many cats, the extent of the pigmentation and thickening progresses over many years, and eventually the tumor may cause glaucoma secondary to trabecular occlusion. Enucleation may then be necessary. (Courtesy pathology archives, Ontario Veterinary College.)

Fig. 20-71 **Diffuse iris melanoma, iris, cat.** Note the extreme variation in cellular morphology: threefold variation in cellular size, nuclear gigantism, and variation in cell shape from round to spindle. The marked variation in the histologic and cytologic appearance of this tumor from case to case has no proven prognostic significance. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Rarely, cats will develop caninelike nodular uveal melanocytomas (and dogs will occasionally develop felinelike diffuse melanomas).

Iridociliary tumors vary from well-differentiated papillary adenomas to solid carcinomas. They all arise from the neuroectoderm of the posterior iris or ciliary body. The histologic distinctions have no apparent relevance to biologic behavior, because all of these tumors are benign. These are relatively common intraocular tumors in dogs (second in frequency only to melanocytoma), are occasionally seen in cats, and infrequently seen in other species. They usually grow as discrete, expansile nodules that protrude into the posterior chamber and are thus visible through the pupil. They are populated by cuboidal and columnar epithelial cells resembling normal iridociliary epithelium and usually form cords and papillary structures reminiscent of disorganized ciliary processes (Fig. 20-72). Some have a more primitive cytologic and histologic appearance, but extraocular metastasis is so rare as to be nonexistent. Even small tumors may become clinically significant because they habitually produce fibroblastic and angiogenic growth factors that stimulate the development of preiridal fibrovascular membranes, causing secondary glaucoma or intractable hyphema.

**Fig. 20-72 Iridociliary adenoma, well-differentiated, posterior chamber, dog.** Although almost always benign, even small tumors of this type may induce the formation of a preiridal fibrovascular membrane that leads to secondary glaucoma. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

1399

**Fig. 20-73 Primary ocular sarcoma, eye, sagittal section, cat.** A solid white stromal sarcoma surrounds remnants of a ruptured lens. Wrinkled remnants of the lens capsule are still visible near the posterior margin of the tumor. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Medulloepithelioma is a relatively rare congenital counterpart of iridociliary adenoma. It has the distinction of being the most common primary intraocular tumor of horses. The histologic appearance reflects its embryonic origin from primitive neuroectoderm still capable of both iridociliary and retinal differentiation. The tumor is populated by hyperchromatic cuboidal cells that make structures reminiscent of ciliary processes and sometimes tubular structures resembling the rosettes seen in retinal dysplasia. In horses, they often incorporate foci of cartilage, bone, and even brain tissue; these are known as teratoid medulloepitheliomas. Although they are by definition congenital tumors, their growth is slow and they may not be diagnosed until many years later.

Feline primary ocular sarcoma (posttraumatic sarcoma) is a high-grade spindle cell neoplasm that probably arises from lens epithelial cells that have escaped through ruptures in the lens capsule. These cells routinely undergo fibroblastic metaplasia as part of ineffective wound healing (see discussion on phacoclastic uveitis), but only in cats does the metaplasia progress to outright sarcoma. The tumor begins as a distinctly perilenticular mass and then grows to fill the globe (Fig. 20-73). As with histologically similar postvaccinal sarcomas, these tumors may have fibroblastic, osteoblastic, or cartilaginous areas in the same tumor (Fig. 20-74). The interval between trauma and detection of tumor can be many years, but the key word here is “detection.” It is very common for cats with this tumor to be presented for veterinary attention only after the tumor has filled the globe. We do not know the rapidity of microscopic tumor development following

## Pathologic Basis of Veterinary Disease, 4th Edition

injury. These tumors frequently invade the optic nerve and then extend into the brain. They are also capable of distant metastasis.

**Fig. 20-74 Primary ocular sarcoma, eye, cat.** Pleomorphic fibroblast-like cells, thought to be derived from lens epithelium, lie adjacent to remnants of lens capsule (*left*). Virtually all cases are preceded by rupture of the lens capsule. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Neoplasms metastatic into the globe are much less frequent than tumors originating within the globe. Virtually any metastatic neoplasm can localize within the uveal tract and spread from there into other portions of the globe. Their histologic appearance is the same as that of the primary tumor. By far the most prevalent is lymphoma (lymphosarcoma), seen in many species but particularly prevalent in cats. It causes diffuse thickening and pallor of the iris and less frequently the choroid. It is clinically almost indistinguishable from severe idiopathic uveitis, and the distinction is usually made on the basis of additional clinical evidence.

### 20.2.5 DISEASES OF THE LENS

#### 20.2.5.1 ANOMALIES OF LENS

The lens is derived from the thickening of the ectoderm induced by contact with the primary optic vesicle. This lens placode then migrates inwardly to cause the optic vesicle to invaginate upon itself to form the primary optic cup. As it does so, the lens placode grows to become a lens vesicle and separates from the overlying ectoderm, which will become corneal epithelium (Fig. 20-29). This vesicle initially is just a single layer of cuboidal epithelial cells surrounded by a very thin capsule. The epithelial cells along its posterior surface elongate to obliterate the lumen of this primitive vesicle, creating the primary lens fibers that will persist throughout life as the lens nucleus. The subsequent development of the cortical fibers of the postnatal lens depends entirely on mitotic activity from the anterior lens epithelium. No epithelium remains along the posterior half of the lens any time after the stage of the primary lens vesicle.

1400

1401

## Pathologic Basis of Veterinary Disease, 4th Edition

Anomalies of the lens are of minor importance when contrasted with anomalies of other portions of the globe. The lens has a central inductive role in ocular development, so significant anomalies of the lens are almost always accompanied by multiple ocular anomalies, such as microphthalmia. It is likely that many of the lens anomalies reflect acquired degenerative changes (even if occurring in utero), resulting in regression of what was a normally developing lens. Such changes include an abnormally small lens (microphakia), an abnormally shaped lens (lenticonus and lentiglobus), and a congenital lens luxation, which is presumably secondary to some congenital abnormality in the zonules.

20.2.5.2

### LENS LUXATION

Dislocation of the lens may be partial (subluxation) or complete (luxation). It may fall forward into the anterior chamber, or it may remain trapped in the posterior chamber. A completely dislocated lens is likely to develop a diffuse cataract, presumably because of its inadequate access to aqueous humor. Anterior lens luxation (Fig. 20-75) is much more significant because it predisposes to glaucoma (see under Glaucoma). Lens luxation may be primary or secondary.

**Fig. 20-75 Anterior lens luxation, eye, sagittal section, dog.** The dislocated, swollen lens has moved anteriorly to lie against the posterior surface of the cornea and has compressed the iris, creating pupillary blockage and secondary glaucoma. There is coagulation and opacification of the aqueous humor and the vitreous because of increased protein from inflammation. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

*Primary lens luxation* refers to that occurring without any known trauma or other ocular disease. It may be congenital or it may be seen later in life. Congenital luxation is usually the result of a developmental error that causes abnormal or insufficient zonules. Much more prevalent are spontaneous luxations that occur in

## Pathologic Basis of Veterinary Disease, 4th Edition

---

young adult dogs of specific breeds (notably terriers). The luxation is almost always bilateral, even if not simultaneous in onset. The ultrastructural and biochemical defect within the lens zonules have not been defined.

Secondary lens luxation is almost always a manifestation of blunt trauma, that causes avulsion of the zonules, or excessive stretching of zonules within a globe that has become greatly enlarged secondary to glaucoma. It may also occur as a result of lysis of zonules by neutrophil enzymes or perhaps bacterial proteases in septic endophthalmitis.

The potential consequences of lens luxation are numerous, but the most significant is glaucoma. This is particularly frequent with anterior lens luxation. The pathogenesis may involve several factors including anterior dislocation of the vitreous causing pupillary block and accumulation of degenerate zonular material within the trabecular meshwork. It is sometimes impossible to decide whether the luxation caused the glaucoma, or the glaucoma caused the luxation.

### 20.2.5.3 DIABETIC CATARACT

Rapidly progressing bilateral cataracts develop in at least 70% of spontaneously diabetic dogs (but not in cats). Progression to complete cortical opacity usually occurs within a few weeks. The swelling may be so rapid that the lens actually ruptures. The pathogenesis of the cataract has traditionally been ascribed to the excessively high level of glucose within the aqueous. Glucose is normally the major energy source for lens fibers via anaerobic glycolysis. When the rate-limiting enzyme of this pathway, hexokinase, is overloaded with glucose, most of the excess glucose absorbed by the lens is shunted to the sorbitol pathway where it is transformed into the polyalcohol sorbitol, which is then slowly reduced to a ketose. Sorbitol may accumulate to very high concentrations within the lens where it osmotically attracts water, resulting in rapid swelling of the lens and disruption of its critical architecture. Sorbitol-induced osmotic disruption alone is not sufficient to explain all of the structural and metabolic changes in sugar-induced cataracts. The efficacy of antioxidants in slowing the progression of such cataracts, the nature of intralenticular biochemical alterations, and detection of increased intralenticular oxidants all point to some kind of oxidative damage as an additional promoter of cataracts.

1401

### 20.2.6 DISEASES OF THE RETINA

1402

#### 20.2.6.1 RETINAL ANOMALIES

##### 20.2.6.1.1 Retinal Dysplasia

Retinal dysplasia is a general term denoting an abnormal retinal differentiation characterized by jumbling of retinal layers. In the past, the term has been used rather loosely to include not only the rare genuine primary developmental anomalies, but also postnecrotic and/or postinflammatory retinal scarring within the developing retina, and retinal folding without any true disorganization. They should be considered as separate entities.

Primary retinal dysplasia is a rare anomaly that probably results from improper induction of retinal maturation by the RPE. Whether the failure relates to delayed and/or inadequate apposition between the two layers or a failure in the production of appropriate signaling molecules by the RPE is not known. The result is a retina with patchy-to-diffuse jumbling of the retinal layers ([Fig. 20-76](#)). Primary retinal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

dysplasia as the sole anomaly is seen as an inherited disease in a few breeds of dogs, but most examples are a part of multiple ocular anomalies. The significance of the lesion varies with the extent of dysplasia. Such retinas are prone to detachment (and in severe cases, the retina may never have been attached at all).

Postnecrotic retinal dysplasia is a much more frequent phenomenon, seen as a sequel to acquired retinal necrosis of the developing retina. In dogs and cats, the period of susceptibility extends for at least 6 weeks after birth, during which time the retina continues to develop. Most of the documented examples are sequelae to viral infection, but in theory virtually any kind of retinal injury during its development could result in postnecrotic retinal “dysplasia.” In contrast to the adult retina, which retains no mitotic capability within the neurons of its various layers, the developing retina can still react with at least some neuronal regeneration. Such regeneration is usually mixed with glial scarring and does not restore perfect retinal architecture (Fig. 20-77).

**Fig. 20-76 Primary retinal dysplasia, retina, puppy.** The cells of the retinal layers are poorly organized and arranged haphazardly, sometimes creating acinar-like structures known as retinal rosettes. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The viruses most often implicated in causing retinal dysplasia in domestic animals are bovine virus diarrhea virus in cattle, bluetongue virus in sheep, herpesvirus in dogs, and both parvovirus and choroid virus in cats. The histologic lesions can be quite variable, but usually there is a combination of very subtle residual inflammation along with postnecrotic scarring in the retina, optic nerve, and perhaps the choroids. Only if these viral infections damage the retina while its neurons still have proliferative capacity, will there be additional findings of disorganized neuronal proliferations with blending of nuclear layers. Proliferation also occurs in the RPE, which may be stimulated to migrate into the overlying scarred retina or to proliferate in situ as plaques of fibroblast-like cells. The pathogenesis of the “dysplasia” is the same as for lesions caused by these agents in the brain—infection, and subsequent destruction of neurons (and possibly other cell types). The dysplasia is not specific to the mechanism of the cellular injury; it reflects only the unsuccessful attempts at postnecrotic healing in a retina still capable of at least some neuronal replication.

## Pathologic Basis of Veterinary Disease, 4th Edition

The window of susceptibility for the development of retinal dysplasia depends on the species (simply because the timetable for retinal development varies with the species). Infection of calves with bovine virus diarrhea virus between 79 and 150 days gestation regularly results in postnecrotic retinal dysplasia, which is the most frequent and certainly the most studied of the virally induced retinal dysplasias. The initial ocular lesion is necrotizing lymphocytic endophthalmitis with random retinal necrosis. The inflammation gradually subsides, so there is scant evidence of inflammation in fetuses aborted later or in dead neonatal calves. Those ocular structures (cornea, uvea, optic nerve) that are already well differentiated at the time of the endophthalmitis may remain normal or exhibit some postnecrotic scarring; only the retina will exhibit abortive efforts at regeneration. Because the peripheral retina remains mitotically active for several weeks after the central retina has matured, dysplastic lesions may be found only in the peripheral retina. It is said that all calves with BVD-associated retinal dysplasia will also have cerebellar hypoplasia. The same is probably true of cats with retinal dysplasia caused by in utero or perinatal infection with panleukopenia virus.

1402

1403

**Fig. 20-77 Postnecrotic retinal dysplasia (so-called), in utero bovine viral diarrhea (BVD) virus infection, retina, calf.** There is loss of nuclei from all retinal layers as a sequela to the in utero destruction of retinal neurons by BVD virus. In some instances, this loss is followed by efforts at retinal regeneration, resulting in disorganization that may be considered as a retinal dysplasia. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Retinal folding is by far the most common type of so-called retinal dysplasia. The great majority of such lesions are seen in juvenile purebred dogs. Most examples are inherited as autosomal recessive traits (sadly, so common in some breeds that they are now accepted as “normal variants”). The ophthalmoscopic findings and effect on vision vary from breed to breed. The histologic lesion is different from true retinal dysplasia and postnecrotic retinal dysplasia in that there is no jumbling of retinal layers, and there is no scarring. The exact pathogenesis for these retinal folds has not been determined, and it may not be the same among all breeds. What seems logical, however, is that the retinal folds represent nothing more than buckling of excessive retina within a globe because growth of the retina has been greater than that of the surrounding choroidal/scleral shell (Fig. 20-78). Supporting this speculation is the observation that such retinal folds are often transient and disappear as the puppy ages (implying that the growth rate of the scleral shell finally “catches up” to that of the retina). The most severe examples occur in dogs with developmental retinal nonattachment. These have extensively folded retinas because the distance from optic disc to ora ciliaris in a straight line is shorter than the convex route taken by a normally attached retina.

**Fig. 20-78 Inherited retinal folds and retinal detachment, eye, posterior chamber, dog.** The acinar-like structures (*arrows*) within the detached retina are transverse sections through retinal folds. These folds probably arise because the growth rate of the retina temporarily exceeds that of the sclera, forcing the retina to fold on itself. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

20.2.6.1.2

### Optic Nerve Hypoplasia

The true frequency of optic nerve hypoplasia is unknown. Most examples are seen in toy breeds of dogs, with the diagnosis being made by clinical examination. Because there is no apparent visual defect, these eyes are almost never available for histologic assessment and the exact nature of the defect (true hypoplasia versus atrophy) remains unknown. Genuine hypoplasia of the optic nerve is the expected result of prenatal or neonatal destruction of ganglion cells from any intraocular disease (including congenital glaucoma, viral infection, and neonatal septicemia with embolic endophthalmitis). The lesion should therefore be correctly classified as atrophy rather than hypoplasia, although the distinction becomes muddy when talking about injuries in the prenatal and perinatal periods.

A distinctly different pathogenesis explains optic nerve hypoplasia in calves born from cows with vitamin A deficiency or in young calves with persistent perinatal dietary deficiency. Atrophy of the nerve results from compression as it passes through an abnormally flattened foramen. The reason for the flattening is improper regulation of osteoblastic activity around the periphery of the developing foramen. Optic nerve damage is not seen if the deficiency in vitamin A occurs after 2 years of age.

20.2.6.2

### ACQUIRED RETINAL DISEASE ([TABLES 20-4](#) AND [20-5](#))

20.2.6.2.1

#### Canine Progressive Retinal Atrophy

Progressive retinal atrophy is the traditional designation for a large group of inherited bilateral degenerative retinopathies of dogs. These have become widespread because of deliberate restrictions of

## Pathologic Basis of Veterinary Disease, 4th Edition

genetic diversity imposed by current line-breeding practices in purebred dogs. Innumerable breeds are affected, and the list grows daily. They all have a similar clinical and microscopic appearance, but that is where the uniformity ends. In reality, this group of diseases includes a genetically and biochemically diverse collection of photoreceptor dysplasias and degenerations that looked similar only when our methods of detection were limited to ophthalmoscopic evaluation and histopathologic examination. Its inclusion here as an acquired retinal disease rather than as a developmental disease is in deference to its clinical presentation and because at least some of this group are indeed true degenerations.

1403

1404

**Table 20-4 Acquired Retinal Diseases (Classified by Lesion)**

<b>Photoreceptor Atrophy</b>	<b>Ganglion Cell Atrophy</b>	<b>Full-Thickness Necrosis</b>	<b>Retinitis</b>	<b>Other</b>
PRA	Glaucoma	High pressure glaucoma (dogs only)	Localization of systemic infections	Storage diseases
Retinal detachment	Optic nerve injury (dieback)	Ischemic injury	Bystander reaction to endophthalmitis	Anomalies
Light-induced retinopathy		Vascular hypertension		
Drug toxicity		Vascular occlusion (thromboemboli, tumor)		
Nutritional deficiency				
Choroidal ischemia				
PRA, Progressive retinal atrophy.				

**Table 20-5 Acquired Retinal Diseases (Classified by Pathogenesis)**

<b>Ischemia</b>	<b>Inflammation</b>	<b>Trauma</b>	<b>Toxic/Metabolic</b>	<b>Developmental Error</b>
Glaucoma*	Hematogenous infection	Detachment	Inherited photoreceptor dysplasias/degenerations	Retinal dysplasia
Detachment	Infection via penetrating injury	Hemorrhage/Infarction	Nutritional deficiency	
Hypertension	Bystander injury from endophthalmitis	Optic nerve trauma/dieback neuropathy	Light-induced retinopathy	
Thromboembolism/metastasis			Neuronal storage diseases	

\* The role of ischemia in glaucomatous retinal atrophy is controversial and probably varies by type of glaucoma and by species.

The stereotypic features seen by light microscopy are loss of photoreceptor outer segments followed by progressive loss of inner segments and eventually loss of neurons from the outer nuclear layer. The result is collapse and thinning of the retina. Other portions of the retina remain normal, and there is no inflammation.

Currently, these bilateral noninflammatory photoreceptor dysfunctions are divided into developmental photoreceptor dysplasias and later-onset purely degenerative diseases. The classification of these various syndromes is under continuous review because in some cases what was once thought to be a degenerative disease affecting previously normal photoreceptors has been discovered to be an inborn biochemical error with a delayed phenotypic manifestation. The list of breeds in which photoreceptor dysplasia or degeneration has been described grows daily, so this brief discussion is not intended to be inclusive.

20.2.6.2.2

### Photoreceptor Dysplasias

The majority of the photoreceptor dysplasias cause clinical signs of bilateral, progressive blindness in juvenile dogs. The fundamental defect varies by breed; the defect may specifically target rods or cones, or affect both. Most examples have a simple, autosomal recessive inheritance pattern. The most thoroughly studied is the combined rod-cone dysplasia of Irish setter dogs. It is beyond the scope of this text to discuss all of the various photoreceptor dysplasias, so this one example will serve to illustrate the general model.

Rod-cone dysplasia of Irish setters is inherited as a simple autosomal recessive trait. Dogs homozygous for the defect have arrested differentiation and then deterioration of the rod external segments, with cones being much less affected. The defect is detected ultrastructurally as early as 16 days after birth, at which time the outer rod segments adjacent to the retinal pigment epithelium should be developing. There is essentially diffuse loss of all rod photoreceptors by 12 weeks of age. This is followed by loss of cones and cells of the outer nuclear layer. The central retina is affected earlier and more severely than is the peripheral retina. Biochemical abnormalities are detected as early as 1 week of age. There is a severe deficiency of the activity of the phosphodiesterase responsible for the continuous hydrolysis of cyclic guanine monophosphate (cGMP) within outer segments. This results in a tenfold excess of cGMP, which has been shown to be toxic to photoreceptors in vitro, and also inhibits photoreceptor development. The basic defect is defective messenger RNA in the gene encoding the outer segment-specific phosphodiesterase.

20.2.6.2.3

### Photoreceptor Degenerations

*Photoreceptor degeneration* refers to an equally diverse group of diseases in which early development is (as far as we can currently detect) normal, and degeneration occurs later in life. Prototype for this group is a rod-cone degeneration in toy and miniature poodles (with virtually identical diseases seen in English and American cocker spaniels, Labrador retrievers, and Portuguese water dogs). This disease is classified as a true degeneration in that photoreceptor differentiation seems to be normal until 6 to 9 weeks of age. After this time, and progressing at an unpredictable rate, photoreceptor outer segments degenerate. Rods are affected earlier and with greater severity than are cones. The disease progresses at an unpredictable rate; affected dogs may not have clinical or ophthalmoscopic evidence of disease until 3 to 5 years of age (which, in breeding dogs, means that they will already have passed on the genetic defect). The macroscopic and histologic lesions begin centrally, around the optic disc, but eventually (by 6 to 7 years of age) the entire retina is affected and the dog is blind. The biochemical basis for the degeneration remains unknown.

1404

1405

20.2.6.2.4

### Inherited Retinal Degeneration and Dysplasia in Other Species

Inherited retinal dysplasias and degenerations have been reported as sporadic occurrences in a variety of cat breeds, but only in the Abyssinian breed has the syndrome been adequately studied. In this breed, there are two different diseases: early onset rod-cone dysplasia and late onset retinal degeneration affecting rods much sooner than cones. The early onset dysplasia is inherited as an autosomal dominant trait and is almost identical to the rod-cone dysplasia of Irish setter dogs. Retinal function deteriorates rapidly, with virtually all affected cats being blind before 1 year of age. In contrast, the late onset retinal degeneration is inherited as an autosomal recessive, and affected cats usually show no clinical signs until

## Pathologic Basis of Veterinary Disease, 4th Edition

---

about 2 years of age; they may retain at least some useful vision throughout life. The earliest structural changes are loss of neurons from the outer nuclear layer and disintegration of rod outer segments.

Congenital stationary night blindness in horses (nyctalopia) is a poorly documented disease affecting the Appaloosa breed (occasionally others). At least in Appaloosas, it seems to be inherited. The visual defects and associated behavioral abnormalities are seen in foals in dim light. In most cases, it does not progress sufficiently to cause obviously defective vision in daytime. Retinal histology is normal.

20.2.6.2.5

### Other (Noninherited) Photoreceptor Diseases

Sudden acquired retinal degeneration (SARD) is an enigmatic, rapidly progressing, photoreceptor degeneration that is histologically identical to those of the inherited progressive retinal atrophies. Blindness occurs very rapidly (over a period of a few days to a few weeks). Affected dogs are adult or even elderly, and the disease can affect any breed or crossbreed. The fundoscopic lesion is bilaterally symmetric and diffuse across the retina. Histologic studies of the early lesions are very few because there is no ethical justification for the surgical removal of these globes as the dogs are otherwise healthy. The disease has not been experimentally reproduced. The cause is unknown, but its occurrence is sometimes associated with polyuria, polydipsia, elevated serum cholesterol concentration, and increased serum alkaline phosphatase activity. Some, but not even the majority, of the affected dogs have adrenal cortical hyperfunction. How this malfunction causes the irreversible retinopathy, if indeed it does, is unknown. One small study demonstrated circulating, complement-fixing antibody to retinal S-antigen and interphotoreceptor retinoid-binding protein, raising the possibility that the disease is a cytotoxic autoimmune phenomenon.

Light-induced retinopathy is an important cause of blindness in animals maintained under inappropriate lighting conditions. The intensity and especially the duration of the light are important. Those species which, in their natural habitat, are preferentially nocturnal are particularly susceptible. The most susceptible group of all are deep-water fish maintained in aquariums with continuous artificial lighting or in shallow outdoor tanks without protection from sunlight. Outbreaks of blindness in different species of laboratory animals (especially albino rats) housed under continuous fluorescent lighting were the first to focus attention on this phenomenon.

The initial lesion is disruption of rod outer segment disks, followed by destruction of all photoreceptors and then their nuclei. At higher light intensities, but still within the range for “normal” room lighting, there may also be damage to neurons of the inner nuclear layer, and to astrocytes and Müller cells. The histologic changes are the same as those for most other photoreceptor diseases, so this specific etiologic diagnosis is made based on the circumstantial evidence of abnormally bright light or an inappropriate balance between high-light and low-light intervals. The mechanism by which “ordinary” light damages the retina is still incompletely understood. Even normal vision is a “destructive” event, with light activation of photopigments generating a lot of free radicals and requiring physiologic replacement of photopigments and photoreceptor membrane discs during periods of sleep. The most popular theory is that of light-induced excessive oxidation of the very abundant polyunsaturated long-chain fatty acids of the rod discs, with the generation of free radicals. These cause cell membrane damage, and without adequate dark intervals there is reduced opportunity for regeneration.

1405

Taurine deficiency as a cause for photoreceptor degeneration is seen only in cats. It is now largely a historical disease because all commercial feline diets are supplemented with taurine. Cats are unable to synthesize taurine from cysteine in amounts adequate for retinal function. Cats eating inappropriate diets (most often, stealing dog food) develop focal retinal atrophy in a horizontal streak dorsal to the optic

1406

## Pathologic Basis of Veterinary Disease, 4th Edition

---

disc. The disease, at least in some cases, progresses slowly to generalized retinal atrophy and blindness. The clinical features are identical to those of a historical disease known as feline central retinal degeneration. It is now assumed that the two diseases are the same, but that may not be true in every single case. The histologic lesion is photoreceptor degeneration, initially involving cone outer segments, but eventually affecting rods as well. The rods of the peripheral retina are the last to degenerate.

Hypovitaminosis A as a cause for retinopathy is occasionally seen in groups of cattle or pigs receiving a ration deficient in vitamin A over a prolonged interval. Because most pastures have more than adequate vitamin A, deficiencies in cattle are likely to be seen only in animals raised in confinement and fed a poor quality ration (especially hay or grain that has been stored for a very long time). In adult animals, the effects of hypovitaminosis A first involve photoreceptor outer segments, slowly progressing to diffuse photoreceptor atrophy, loss of the outer nuclear layer, and eventually to complete retinal atrophy. These lesions have been reproduced in all domestic animals by feeding them specially formulated diets, but naturally occurring retinal lesions are seen almost exclusively in cattle. The deficiency of vitamin A results in a deficiency of rhodopsin within the photoreceptors. The initial ultrastructural lesion is swelling, followed by disintegration and fragmentation of the outer segments. Initially this can be reversed with vitamin A therapy until inner segments have also been affected.

Ischemic retinopathy may occur as a sequela to vascular occlusion within the retina itself or within the choroidal vasculature by tumor metastases or thromboemboli, as a sequela to retinal detachment, or as one of the mechanisms for retinal atrophy in glaucoma. Retinal ischemic injury may also occur subsequent to retinal or choroidal vasculitis associated with immune disease or a few infectious diseases, such as thrombotic meningoencephalitis of cattle or Rocky Mountain spotted fever or ehrlichiosis in dogs (Fig. 20-79). The microvascular disease associated with diabetes mellitus is an exceedingly important cause of ischemic retinopathy in human beings, but examples in domestic animals with spontaneous diabetes are rare.

Vascular hypertension is an additional and relatively common cause for devastating retinal ischemic damage in dogs and cats. It is usually secondary to chronic renal failure. At least 60% of dogs with chronic renal failure are hypertensive.

**Fig. 20-79 Choroidal vasculitis with thrombosis, choroid and retina, horse.** Dilated choroidal blood vessels contain fibrin thrombi and are surrounded by edema and some hemorrhage. There is ischemic necrosis of the overlying retina. The horse retina, with its very limited intrinsic vasculature, should theoretically be more susceptible to infarction secondary to choroidal vascular disease than the retina of any other domestic mammal. Such lesions are occasionally seen with disseminated intravascular coagulation regardless of the pathogenesis, as well as with idiopathic coagulopathies. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

The clinical disease is characterized by hemorrhage within the retina or from the retina into the posterior vitreous and retinal detachment secondary to serous effusion from injured retinal and choroidal blood vessels. The histologic lesions are primarily in retinal and choroidal vessels, but they may be found throughout the uvea. Characteristic changes are most easily found in the small retinal muscular arteries and larger arterioles. The vessel lesions include mural edema that may progress to fibrinoid necrosis of the tunica media and perivascular fibrosis. Muscular hypertrophy may occur in larger vessels, particularly those of the choroid. Changes occurring as a consequence of the vascular damage include localized retinal necrosis, serous retinal separation with resultant atrophy of photoreceptors and hypertrophy of retinal pigmented epithelium, and intraretinal hemorrhage (Fig. 20-80). There may be necrosis and/or repair of cells of the RPE, and sclerosis within the choroid. The severity of the retinal necrosis varies from focal infarcts in the inner retina to (more commonly) extensive full-thickness hemorrhagic infarcts in large segments of retina. The larger lesions probably reflect the effects of widespread choroidal and retinal vascular degeneration. At least some of the retinal lesions are not the direct result of vascular necrosis, but are the result of exaggerated autoregulatory vasoconstriction of precapillary sphincters attempting to protect the retinal capillary bed from the systemic hypertension. Sustained vasoconstriction leads to ischemic necrosis of the deprived retina, RPE or choroid, and necrosis of vascular endothelium distal to the constricted precapillary sphincters. Any blood that does manage to pass through the constricted sphincters into the capillaries enters blood vessels already

1406

1407

## Pathologic Basis of Veterinary Disease, 4th Edition

damaged by a drop in perfusion pressure, so there is inevitable transmural leakage of serum and even blood.

**Fig. 20-80 Retinal hypertensive vasculopathy, retina, dog.** There is fibrinoid necrosis of the retinal arteriole and nonselective ischemic necrosis of the surrounding retina. The dog had end-stage retinal disease. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

### 20.2.6.2.6 Retinitis

Retinitis as the sole ocular lesion is rare. When it does occur, however, it is almost always in the course of neurotropic virus infections, such as canine distemper, rabies, and pseudorabies. Additional diseases that frequently cause prominent retinal lesions (albeit virtually never retinal lesions alone) include toxoplasmosis, canine ehrlichiosis and Rocky Mountain spotted fever, and thrombotic meningoencephalitis of cattle (Fig. 20-81). The lesions in the retina are the same as those in any the other tissue affected by these systemic diseases. Retinal lesions also occur in the course of visceral larval migrans caused by the migration of the larvae of *Toxocara canis* and *Baylisascaris procyonis*.

### 20.2.7 DISEASES OF THE EYELIDS

#### 20.2.7.1 DEVELOPMENTAL ANOMALIES

Anomalies in the formation of eyelids, including the shape of the palpebral fissure, are exceedingly common in dogs because “eye shape” has been so extensively manipulated during the evolution of the various breeds. In some instances, the “anomaly” is even a required feature for the breed (as with ectropion in Bloodhounds and Saint Bernards, for example). Most of these anomalies are not examined microscopically because they are macroscopically obvious. They are important in clinical ophthalmology, and so they are considered in much greater detail in clinical textbooks than they are here.

**Fig. 20-81 Suppurative embolic retinitis, retina, steer.** There is focal obliteration of the retina by a combination of necrosis and inflammation. The leukocytes extend through the outer nuclear layer into subretinal space. This lesion is common in bovine thrombotic meningoencephalitis but is occasionally seen in other bacteremic or septicemic diseases. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

### 20.2.7.1.1 Eyelid Agenesis and Coloboma

Particularly in cats, there may be partial or complete absence of an eyelid. The most common by far is a partial defect (i.e., coloboma) involving only the upper eyelid. The notchlike defect results in localized corneal desiccation followed by cutaneous metaplasia.

### 20.2.7.1.2 Premature Eyelid Separation

The normal fusion of eyelids (known as physiologic ankyloblepharon) in carnivores is essential to protect the immature cornea from infection and desiccation. Premature eyelid separation (technically a “maldevelopment” because it occurs before the maturation of the globe) seriously predisposes the eye to infectious keratitis, desiccation, and even corneal rupture.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 20.2.7.1.3 Entropion and Ectropion

Entropion is the inward rolling of the eyelid margin because of inadequate overall length. The usual result is irritation of the cornea by the eyelid skin, cilia, and/or hair. It is a very common anomaly in purebred dogs because they have been selected for breeding based partly on the shape of the palpebral fissure, which is a factor in determining facial “expression.” The extent and magnitude of the defect varies greatly among individual animals, but tends to be relatively uniform within an affected breed. Clinical textbooks have extensive accounts of the manifestations of entropion and ectropion in different breeds and the innumerable techniques for their repair. The outcome for the cornea varies from corneal cutaneous metaplasia to outright ulceration, depending on the severity of the irritation. Entropion may also be acquired as the result of inflammation and subsequent contracture of a scar in the eyelid.

1407

1408

Ectropion is created by undue laxity of an excessively long eyelid, resulting in an outward gaping of the eyelid margin. As with entropion, its extent and severity vary greatly among individual animals and among breeds. The lower eyelid is more frequently affected to a clinically significant degree than the upper, presumably because the effect of gravity on the upper eyelid makes ectropion there less obvious. The anomaly has less significance than entropion because there is no direct corneal irritation. The protruding conjunctiva may entrap debris and become chronically inflamed and because of the failure of the lids to close properly, there may be some chronic exposure keratitis.

### 20.2.7.1.4 Anomalies of Eyelashes: Trichiasis, Distichiasis, and Ectopic Cilia

These are prevalent in dogs and may or may not cause clinical signs, depending on whether they irritate the cornea or not. They are mentioned here only for the sake of completeness because these are almost never evaluated histologically. Distichiasis is the presence of an ectopic row of cilia originating from the ducts of the Meibomian glands. The defect is usually bilateral. It may be clinically silent or cause corneal irritation. Trichiasis is misdirection of the normal cilia, so that they contact the cornea. Ectopic cilia are abnormally placed cilia within the lamina propria of the conjunctiva. Their emergence through the palpebral conjunctiva may result in profound corneal irritation.

### 20.2.7.2 ACQUIRED DISEASES

Chalazion is sterile granulomatous inflammation in response to the leakage of Meibomian secretion into the surrounding dermis. It is much more common in dogs than in any other species. Although it can theoretically occur in response to any type of injury to the Meibomian gland, in almost all cases, the inflammation is found adjacent to Meibomian adenomas. Histologically the inflammation is an accumulation of large foamy macrophages and multinucleated cells around the abnormal Meibomian gland. Some of the lipid may occur in the form of extracellular lakes of unstained free lipid, especially in cats. The macrophages contain distinctive slender, birefringent, intracellular crystals, which are readily visible under polarized light.

Idiopathic granulomatous marginal blepharitis is seen only in dogs as a series of coalescing nodules that eventually create a diffuse thickening of one or both eyelid margins. The histologic lesion is a coalescence of suppurating granulomas in the subconjunctival tissue of the eyelid margin, without any proven association with any particular adnexal structure, such as a Meibomian gland or hair follicle. The lesion is very similar to those of cutaneous sterile pyogranuloma syndrome and other idiopathic granulomatous panniculitides, for all of which the pathogeneses are unknown. No infectious agent has ever been identified.

### 20.2.7.3 NEOPLASMS OF THE EYELIDS

Meibomian adenoma is by far the most common tumor of the canine eyelid, accounting for in excess of 80% of all eyelid tumors in that species. Eyelid tumors in any other species are infrequent to rare. The tumor is an exact counterpart of sebaceous adenomas seen elsewhere in skin: a smooth expansile growth populated by intermingled basal cells and mature sebaceous cells. The tumor usually retains well-developed lobular architecture and in some cases differs from a normal gland only by its much greater overall size (Fig. 20-82). Many are populated almost exclusively by basal cells with just a few foci of sebaceous differentiation. Many contain substantial amounts of melanin pigment. Behaviorally, they are benign and are easily cured by excision.

Melanocytoma is the second most common tumor of the canine eyelid. It is identical in all respects to superficial dermal melanocytomas found elsewhere in the skin, and it is universally benign (Fig. 20-83).

**Fig. 20-82 Meibomian adenoma, eyelid, dog.** The tumor is a well-demarcated, encapsulated, expansile nodule consisting of intermingled basal and sebaceous cells. The accompanying papillary hyperplasia of the overlying epidermis is a common secondary reactive change. H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

1408

**Fig. 20-83 Cutaneous melanocytoma, eyelid skin, dog.** A nodule of firm black tissue has replaced a wedge of the eyelid skin at its margin. Determining the exact location of the mass is clinically critical because a similar tumor arising even a few millimeters away on the palpebral conjunctiva would probably be behaviorally malignant. (Courtesy Dr. R. Peiffer, University of North Carolina.)

Other neoplasms affecting the eyelid with greater-than-usual frequency include nerve sheath tumors in dogs and cats, squamous cell carcinoma and mast cell tumors in cats, and sarcoids in horses. They are identical in histologic appearance and behavior to those tumors occurring anywhere else in skin.

### 20.2.8 DISEASES OF THE CONJUNCTIVA

#### 20.2.8.1 DEVELOPMENTAL ANOMALIES

##### 20.2.8.1.1 Conjunctival Dermoid

As with corneal dermoid, this is the presence of ectopic hair follicles and adnexal glands within the conjunctiva. Ordinarily, it is the bulbar conjunctiva that is affected. The ectopic tissue ranges from just a few scattered sebaceous glands to mature hair follicles with a full complement of adnexa.

#### 20.2.8.2 ACQUIRED CONJUNCTIVAL DISEASES

##### 20.2.8.2.1 Infectious Diseases

Infectious bovine rhinotracheitis (bovine herpesvirus 1) is usually accompanied by serous to purulent conjunctivitis, which can be confused clinically with infectious bovine keratoconjunctivitis caused by

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Moraxella bovis*. However, corneal involvement with rhinotracheitis is uncommon, and it is never the major presenting complaint and never reaches the severity seen in infectious bovine keratoconjunctivitis. Following the acute serous conjunctivitis, hyperplasia of the resident conjunctival lymphoid nodules (follicular lymphoid hyperplasia) frequently occurs. Macroscopically, this is evident as a series of glistening gray-white protruding nodules a few millimeters in diameter, visible through the epithelium of the bulbar and palpebral conjunctiva.

Feline infectious conjunctivitis is caused by mycoplasma, chlamydia, or herpesvirus. The microscopic lesions are not specific except for the presence of inclusion bodies characteristic of the specific infectious agent. Unfortunately, inclusion bodies are present only during the first few days of disease and are almost never present by the time cytologic or histologic samples are obtained. Thus the presumptive diagnosis is usually based on the clinical characteristics of the conjunctival disease, and especially on the presence of other clinical signs. Because these agents are all quite widely distributed in the healthy feline population, one must use great caution in interpreting a positive result of a serologic or PCR test as indicating a causal role for that organism in the disease in that patient.

Feline herpesvirus 1 causes a combination of conjunctivitis, keratitis, and upper respiratory disease when it first affects young cats, but it may cause conjunctivitis alone as a recurring infection in older cats that have recovered from the initial, more widespread disease. Herpesvirus is a more significant cause of keratitis in cats.

*Mycoplasma felis* and *Mycoplasma gatae* have been reported to cause suppurative, erosive conjunctivitis. However, a review of the available evidence suggests that it is more likely that these mycoplasmas, which are members of the normal feline conjunctival flora, act only as significant opportunists in disease initiated by herpesvirus or chlamydia.

*Chlamydia psittaci* usually causes unilateral conjunctivitis in cats of any age, without any other associated disease. The conjunctivitis is initially neutrophilic but rapidly becomes a subepithelial mixture of neutrophils, macrophages, lymphocytes, and plasma cells. Early in the disease (between days 7 and 14), typical intracytoplasmic inclusion bodies can be seen, and their detection is improved by immunofluorescent staining. Because the clinical signs are characteristic and disease is easily treated, histologic assessment is rarely required. By the time histologic assessment is required in the few cases not responding to therapy, it is too late: The lesions have become completely nonspecific lymphonodular conjunctivitis with no visible inclusion bodies.

Thelazia are thin, rapidly motile nematodes 7 to 20mm in length that inhabit the conjunctival sac and lacrimal duct of a variety of wild and domestic mammals. They are perhaps not exactly “normal” in the conjunctival sac, but only a small proportion of animals infected with the parasite have clinical disease. They are transmitted from animal to animal by face flies, which ingest larvae in lacrimal secretions. In North America, they are of minor significance as parasites of horses, and cause only a mild lymphonodular conjunctivitis.

1409

Fig. 20-84 **Granulomatous conjunctivitis with eosinophils (focal), habronemiasis, conjunctiva, horse.** Note the multiple coalescing eosinophil-rich granulomas within the conjunctival lamina propria. These granulomas are old larval migration tracts, but habronema larvae are rarely visible in them by the time such lesions are sampled for histological examination (usually to rule out neoplasia). H&E stain. (Courtesy Dr. B. Wilcock, Ontario Veterinary College.)

Habronemiasis is a far more significant disease in horses. It causes oozing eosinophilic granulomas, up to one centimeter in diameter, in the palpebral and bulbar conjunctivae. The macroscopic lesion is a firm nodule with yellow, caseous gritty debris in the center. The lesion is in response to nematode larvae deposited by a fly intermediate host, usually *Musca domestica* or *Stomoxys calcitrans*. They are attracted to this location by the moisture collecting in the medial canthus. Larvae of *Habronema muscae*, *Habronema microstoma* or *Draschia (Habronema) megastoma* are also capable of causing the same histologic lesion that is identical to cutaneous habronemiasis, a chronic eosinophilic and granulomatous inflammation surrounding live or dead larvae that are difficult to find in histologic sections (Fig. 20-84).

### 20.2.8.2.2

#### Idiopathic and Immune Diseases

Idiopathic eosinophilic conjunctivitis is probably the conjunctival counterpart of the eosinophilic keratitis syndrome seen in cats and occasionally in horses. Rarely the conjunctival lesion exists without any obvious corneal involvement. Lesions may be unilateral or bilateral. The microscopic lesions are greatly influenced by age and the previous antiinflammatory therapy, so it is hard to know what the “real” lesions are. In biopsy samples, the usual changes include ulceration, epithelial hyperplasia, squamous metaplasia, and a notable lymphocytic infiltration with a large number of eosinophils. The presence of eosinophils is a requirement for the diagnosis. They are not present as part of a granulomatous disease as in habronemiasis, nor are they associated with collagenolysis as seen in insect bite reactions.

## Pathologic Basis of Veterinary Disease, 4th Edition

Protrusion and/or prolapse of the gland of the third eyelid is quite common in dogs and is thought to be the result of laxity in the connective tissue anchoring the gland to the cartilage of the third eyelid. Because the prolapsed mass is unsightly and resembles a neoplasm, it is sometimes excised and submitted for histologic examination, which reveals that the gland is usually completely normal or has mild nonspecific changes in response to desiccation or chronic edema.

Nodular granulomatous episcleritis (NGE) is a prevalent nodular lesion of the conjunctival lamina propria of dogs. It has been known by many names over the years, reflecting confusion about its exact status as an immune-mediated proliferative disease or a histiocytic neoplasm. Some of the synonyms include ocular nodular fasciitis, fibrous histiocytoma, or collie granuloma. It is not known whether this is one disease or several different diseases with the same histologic appearance. The disease is defined by its histopathologic changes: a discrete nodular accumulation of macrophages, fibroblasts, lymphocytes, and plasma cells anywhere in the conjunctival lamina propria. These cells are uniformly intermingled, without the formation of discrete granulomas. There is no collagenolysis, and usually there is not a significant number of granulocytes. The lateral limbus is the most frequent site, but the third eyelid is also frequently affected. In most instances, the lesion is unilateral and solitary, but bilateral involvement is not uncommon.

Necrotic scleritis is another canine idiopathic “immune-mediated” disease that may be mistaken for NGE. It often begins as a nodular thickening of the bulbar conjunctiva or underlying sclera just posterior to the limbus. Microscopically, however, it is a more destructive lesion with collagenolysis and (at least in the early disease) numerous eosinophils in addition to the macrophages, fibroblasts, and lymphocytes, which are also seen in NGE. It is a rapidly progressive and destructive lesion, capable of spreading rapidly to involve large areas of the sclera. Late in the disease it may spread into the globe, causing destructive coalescing granulomas throughout the uvea.

### 20.2.8.3 NEOPLASMS OF THE CONJUNCTIVA

Squamous cell carcinoma is an exceedingly prevalent and economically significant neoplasm affecting the sunlight-exposed, nonpigmented epithelium of the eyelids, bulbar conjunctiva, usually at the lateral limbus and third eyelid of cattle living outdoors in sunny environments. The frequency is highest in areas in which livestock are likely to be exposed to ultraviolet radiation: areas with high altitude and lots of sunshine.

1410

Animals with poor pigmentation of eyelids and conjunctiva are particularly susceptible because this increases the risk of chronic cellular injury from solar radiation. Viruses such as bovine papillomavirus and bovine herpesvirus 5 have been detected within bovine ocular squamous cell carcinomas, but their causal role has not been proven. An identical tumor occurs in horses living in the same environments.

1411

As occurs with sunlight-induced squamous cell carcinoma in other cutaneous locations, the ocular tumor goes through a series of precancerous changes in response to actinic injury. The sequence of lesions is squamous plaque (acanthosis), keratoses (localized foci of hyperkeratosis), squamous papilloma, dysplasia, squamous carcinoma in situ, and eventually invasive squamous cell carcinoma (Fig. 20-85). Keratoses can sometimes develop into cutaneous horns. These are usually conical, can reach a length of a few centimeters, and consist of compacted laminated keratin (Fig. 20-86). Occasionally, they are on the surface of a papilloma. Like actinic keratoses they are considered to be premalignant. The stepwise transition from acanthosis to eventual carcinoma in situ is characterized by increasing nuclear pleomorphism, hyperchromasia, and loss of polarity of the cells and maturational jumbling of cells within the stratum spinosum. The only absolutely unequivocal proof of malignant transformation is invasion by cords of malignant cells through the basement membrane into the underlying lamina propria (Fig. 20-85, C). The

1411

1412

---

mass of invading cells is usually surrounded by an intense lymphocytic-plasmacytic inflammatory reaction, a reaction which is interpreted as an immune response to the developing tumor. Not all precursor lesions develop into carcinomas. The efficacy of the immune response in destroying precursor lesions and early carcinomas is unknown.

**Fig. 20-85 Squamous cell carcinoma, eye and eyelids, Hereford cow. A,** Medial limbus. The carcinoma has spread over the cornea as an exophytic growth from its original site on the medial limbus. Note the corneal edema (*gray area*) adjacent to the margin of the carcinoma. Pigmentation of the eyelids, as shown here, does not protect the conjunctiva or the limbus from developing an actinic (exposure to sunlight) squamous cell carcinoma. **B,** Third and lower eyelids. Note the early exophytic squamous cell carcinoma on the third eyelid, nodules of acanthosis on the lateral half of the lower lid conjunctiva and on the skin of the medial canthus, and keratoses on the lower lid. **C,** Early infiltrative squamous cell carcinoma, lower lid. A small group (*arrow*) of epithelial cells has infiltrated through the basement membrane of the mucosal squamous epithelium. Note that these cells are atypical. The basal cells have lost their polarity and now lie horizontal to the edge of the infiltrating mass instead of vertically, as do normal basal cells (perpendicular to the basement membrane). H&E stain. (**A, B, and C,** Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 20-86 Cutaneous horn, lower eyelid, mucocutaneous junction.** The cutaneous horn on the lower lid is an exaggerated form of a keratosis. The unpigmented skin of the lower lid and medial canthus is erythematous, and the surface of the medial aspect of the lower lid is slightly roughed by white foci of acanthosis. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

In cats, squamous cell carcinoma usually affects the skin of the eyelid itself rather than conjunctiva. Squamous cell carcinoma is inexplicably rare in either the eyelids or the conjunctiva of dogs.

Benign squamous papillomas with no inclination for malignant progression are frequent tumors of the bulbar conjunctiva of dogs. They are formed by multiple slender fronds consisting of conjunctival lamina propria covered by hyperplastic, but otherwise orderly and mature stratified squamous nonkeratinized epithelium. There is often substantial melanin pigment within the basal cells and lamina propria, so these tumors can be mistaken on clinical examination for conjunctival melanomas. There is no evidence that these papillomas are caused by a viral infection.

Primary conjunctival melanomas arise within the epithelium of the bulbar conjunctiva of dogs and cats. In dramatic contrast to the benign melanotic tumors of the haired skin of the eyelid or those arising deeper within the stroma of the limbus (see later discussion), these are aggressively invasive with a high risk of metastasis. They resemble oral melanomas in histologic and cytologic appearance, and in the frequency of being amelanotic. Microscopically, they form solid endocrine-like packets of 20 to 30 cells supported by a delicate fibrous stroma. Intraepithelial clusters (junctional activity) are often present. The cells generally are pleomorphic epithelioid cells with frequent nuclear gigantism and hyperchromasia. They are markedly invasive, a feature often visible in histologic sections. Postoperative recurrence is extremely frequent. Pigment, when present, is most frequently found in tumor cells within or near the epithelium.

Limbal melanocytomas are relatively common tumors in dogs. They are infrequent but not rare in cats. They arise from the pigmented cells within the limbus, which is the junction of the corneal stroma and sclera. They form a slowly expanding, heavily pigmented discrete nodule populated by heavily pigmented large plump cells identical to those seen in the more common anterior uveal melanocytoma. They have no metastatic potential, and surgical excision is curative. They may bulge outwardly to distend the overlying conjunctiva, but histologic examination reveals that they do not infiltrate the epithelium and they are therefore easily distinguished from the more dangerous primary conjunctival malignant melanoma.

Hemangioma and hemangiosarcoma are vascular endothelial neoplasms arising within the conjunctival lamina propria at the lateral edge of the third eyelid, and in the lateral bulbar conjunctiva of dogs, cats, and (occasionally) horses. About 30% of canine cases are bilateral. The sites of predilection and the increased risk of disease in outdoor dogs in sunny climates and high altitudes suggest that this disease is probably triggered by chronic actinic radiation injury (as is true for at least some examples of cutaneous hemangioma and hemangiosarcoma in dogs). Those tumors that are well circumscribed and consist of bland endothelium are classified as hemangiomas, and those formed by hyperchromatic endothelium with at least moderate anisokaryosis and peripheral invasion are classified as hemangiosarcomas. However, there is a continuum in the histologic appearance from hemangioma to hemangiosarcoma. Many are intermediate, or even show a continuum of lesions from benign to malignant within the same tumor. Distinguishing benign from malignant is based primarily on the degree of peripheral invasion. At least in dogs (the species most often affected), this distinction appears to have no behavioral significance, as almost all are benign and surgically curable.

1412

In horses, some (but not all) of the vascular tumors involving the third eyelid are solid primitive hemangiosarcomas. Some of these tumors are very invasive and have a high risk of metastasis to the regional lymph node.

1413

Adenocarcinoma of the gland of the third eyelid is a tumor of very old dogs (rarely cats), which is usually seen as a well-differentiated, slowly expanding tubular adenocarcinoma at the dorsal margin of the third eyelid. It replaces the normal gland of the third eyelid but only slowly invades adjacent tissue. The risk of metastasis is very low.

Lymphoma (lymphosarcoma) occasionally arises within the lamina propria of the third eyelid in animals (most often in cats) that do not have any evidence of disseminated lymphosarcoma. The cells are similar in histologic appearance to those of lymphomas elsewhere, but it takes courage to make this diagnosis when the tumor appears to be present in only a single, unlikely location, such as the third eyelid.

### 20.2.9

#### DISEASES OF THE ORBIT

Orbital cellulitis is not a specific disease but inflammation of soft tissue in response to infectious agents introduced via a penetrating wound, a migrating foreign body, or an inflammatory focus from some adjacent tissue (often, a tooth root abscess). Only rarely does panophthalmitis extend into the orbit to cause orbital cellulitis because the sclera seems to be an effective barrier to the migration of leukocytes and infectious agents.

Lymphocytic interstitial dacryoadenitis is a progressive idiopathic lymphocytic inflammation of the lacrimal gland and/or gland of the third eyelid of dogs. It is present as a histologic lesion in most cases of spontaneous keratoconjunctivitis sicca. The initial lesion is an interstitial lymphocytic infiltration with epithelial necrosis, followed by glandular atrophy and extensive interstitial fibrosis with residual nests of lymphocytes. Because

## Pathologic Basis of Veterinary Disease, 4th Edition

no infectious agent can be found and because the disease can be successfully managed with immunosuppressive therapy (particularly cyclosporin), it is assumed to represent a T-lymphocyte-dependent autoimmune disease.

Orbital extraocular myositis affects all the extraocular muscles except the retractor bulbi. It is a rare disease of dogs. Histologically, there is a lymphocytic myositis that results in myonecrosis, followed by attempts at regeneration and eventually muscle atrophy and fibrosis. The acute disease causes enough swelling to result in pain and exophthalmos. In the chronic disease, there is a notable enophthalmos (retraction of the globe into the orbit). An immune-mediated attack directed specifically against the extraocular muscles is suspected to be the cause of this disorder. Because the extraocular muscles are a difficult site from which to obtain a biopsy, diagnosis is generally based on the typical clinical findings. Corticosteroid therapy is effective, but episodes can recur.

Orbital neoplasms are surprisingly frequent in dogs. They are rare in other domestic animals with the exception of cattle, in which malignant lymphoma occurs. Most orbital tumors are not discovered until they are large enough to cause exophthalmos or blindness, by which time the majority of cases are no longer amenable to surgical cure. Many different tumors in the orbit have been reported, but the only ones that are relatively frequent are optic nerve meningioma and multilobular osteochondroma in dogs, nasal carcinoma and gingival squamous cell carcinoma in dogs and cats, and malignant lymphoma in cattle. These tumors are all histologically identical to those in other locations.
